The fact that no other compound corresponding to carbon oxide (*e.g.*, methylene) has yet been prepared (although many such attempts have been made) tends to show that the variation in valency in this compound is due to the oxygen rather than to the carbon; moreover, the quadrantoxide of silver necessitates, apparently, the possible tetravalency of oxygen.

Evidently this view of the existence of triad atoms, by a combination of which are produced the complexes (ordinarily termed atoms) of which chemical compounds are made up, might be extended to all elements. Thus lead, which is tetravalent in plumbic ethide and divalent in its ordinary compounds, may be considered as being a complex of (Pb_2) where $Pb''' = 103.5$, thus:—

Similarly, thallium may be regarded as a complex (Tl_3) where $Tl''' = \frac{203}{3}$.

Until, however, the vapour densities of the metallic chlorides, &c., be obtained, it is impossible to say that

some of these compounds have not double the molecular formulæ usually attributed to them: *e.g.*, plumbous chloride may be—

instead of $Pb''Cl_2$; and thallous chloride—

instead of $Tl'Cl$; thallic chloride being—

where $Tl''' = 203$.

Hence, at present it is unnecessary to extend this hypothesis to all elements—oxygen, nitrogen, chlorine, and their respective congeners being probably the only ones for which it is required in the present state of our knowledge, and even then only in special cases in the instances of the oxygen and chlorine series.—I am, &c.,

CHARLES R. A. WRIGHT, D.Sc.

Chemical Laboratory, St. Mary's Hospital, W.,
October 2, 1871.

THE "DIAMOND MATRIX."

To the Editor of the Chemical News.

SIR,—I beg to inclose you photograph* of a most interesting and rare geological specimen which was discovered on the Diamond-fields ("Du Toit's Pan.")

It consists of some hundreds of diamonds cemented to a core of foreign substance. Amongst the mass there appear garnets and other bodies. The weight of the entire specimen is 19 carats, and the photograph is a magnificent image 31 times (lineal).

As I hope to be in England about the middle of November, controversy, which is here rife as to its constitution, formation, &c., will, I trust, be set at rest by a full examination and analysis in London of the substances in combination with the gems.

I have several valuable minerals from South Africa, and a vast fund of information regarding the newly discovered diamond-fields, which I must reserve for a time, and hope to lay many subjects of importance before the Chemical Society on my arrival in England.—I am, &c.,

T. W. TOBIN.

Cape Town, South Africa,
September 1, 1871.

VITALITY OF DISEASE GERMS.

To the Editor of the Chemical News.

SIR,—Your correspondent, Richard Weaver (CHEMICAL NEWS, vol. xxiv., No. 619), states, that by his experiments, 350° is the highest temperature which may be used for disinfecting clothing, &c., by heat, without destroying the fabrics.

Dr. Calvert (in previous numbers) in his paper says, that at 400° germ life cannot exist, but I take it that his experiments were conducted at 100°, 200°, 300°, 400°, 500°, and 600° F. only, and that the intermediate temperatures were not tried. If this is the case, it might happen that even at 330° F. germ life will be destroyed, which will consequently render disinfection by heat practicable.

Not having the time or apparatus to repeat Dr. Calvert's experiments myself, I take the liberty of mentioning this.—I am, &c.,

H. B. YARDLEY.

Hudson's Wharf, Victoria Docks,
October 17, 1871.

* The photograph can be seen at our office by anyone interested in the subject.—Ed. C.N.

MISCELLANEOUS.

London Institution.—The first Evening Lecture of the session 1871-72 will be delivered on Thursday, November 2, at half-past seven, by J. H. Gladstone, Ph.D., F.R.S., F.C.S. Subject:—"Michael Faraday: the Story of his Life."

Quality of the Gas Supplied to London.—Dr. Letheby, the Chief Gas Examiner appointed by the Board of Trade, has recently reported to the Corporation of London, and to the Metropolitan Boards of Works, on the quality of the gas supplied to London by certain companies during the quarter which ended on the 30th of September last, from which it appears that the following is the average illuminating power of the gas of each of the Companies at the several testing places. When burnt at the rate of 5 cubic feet an hour, the common gas of the Chartered Company has been equal to 16.64 standard sperm candles at Arundell Street, Haymarket; to 16.84 candles at Gray's-Inn Road, to 17.50 candles at Friendly Place, Mile End; and to 17.59 candles at Cannon Street in the city. The Imperial Company's gas has been equal to 15.73 standard sperm candles at Camden Street; to 16.45 candles at Graham Street; and to 17.06 candles at Oakley Square; and the South Metropolitan Company's gas has been equal to 16.16 candles at the testing place at Hill Street, Peckham. The Cannel gas supplied by the Chartered Company to Cannon Street has been equal to 27.92 standard sperm candles, and at Arundell Street, Haymarket. And with respect to purity, Dr. Letheby reports that the gas of all the companies has been constantly free from sulphuretted hydrogen, except on two occasions, when traces of this impurity were present in the gas of the South Metropolitan Company, but he ascertained from investigations at the works that it was due to accidental circumstances. Sulphur in other form than this was present in the gas of the several companies in very variable proportions. In the Chartered gas (common) it amounted to an average of 29.24 grains per 100 cubic feet of the gas at Gray's-Inn Road; to 30.45 grains at Arundell Street; to 27.97 grains at Cannon Street, and to only 16.21 grains at Friendly Place. In the Imperial Gas it averaged 33.30 grains per 100 feet at Oakley Square; to 26.68 grains at Graham Street, and to 24.37 grains at Camden Street, and in the South Metropolitan gas it averaged 30.12 grains per 100 cubic feet. The Cannel gas of the Chartered Company at Arundell Street contained 25.65 grains per 100 feet, whereas the same description of gas at Cannon Street contained only 9.51 grains of sulphur. Dr. Letheby reported that, in most cases, the proportion of sulphur had been larger during the quarter than in the corresponding quarter of last year. Ammonia was not in any case in excess of the quantity prescribed by the referees.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgement. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, July, 1871.

The following original papers relating to chemistry are published in this number:—

New Method of Preparing Chloride of Antimony, and Production of an Oxide of Antimony Uncontaminated with Arsenic.—Dr. Rieckher.—The preparation of an oxide of antimony

(for medicinal use) quite free from arsenic, and without the evolution of noxious gases, is obtained by treating antimony (metal) with twice its weight of oxide of iron and ten times its weight of crude hydrochloric acid. The neck of the retort wherein the operation is carried on should be connected with the receiver, which renders the use of any lute which might be acted upon by hydrochloric acid unnecessary. The mixture is to be kept boiling for several hours, whereby not only the metal is dissolved but also any arsenic it might contain removed. The receiver should be placed in cold water, a sufficient precaution to condense any hydrochloric acid gas which is evolved.

Sulphuric Acid a Product of the Combustion of Coal-Gas.—Dr. A. Vogel.—The author records a series of experiments made to prove the well-known fact that sulphuric acid is a constant product of the combustion of coal-gas, even when purified as perfectly as possible from sulphuretted hydrogen; the source whence the sulphuric acid is derived is the sulphide of carbon present in the gas.

Detection of Minute Traces of Manganese.—Dr. Böttger.—A few grammes of chemically-pure chlorate of potassa are first fused in a test-tube, and, while fused, there is put into it a minute quantity of the substance, mineral or organic, to be tested for manganese. If at the end of the reaction the contents of the thoroughly-cooled tube exhibit a peach-blossom red colour, the substance thrown into the fusing chlorate of potassa contained manganese, the presence of which may be thus ascertained in wood, human hair (especially the reddish coloured), coal, and minerals, of all of which only minute quantities are required.

Mixtures for Keeping Furs, Woollen Fabrics, and Carpets from being Injured by Moths.—Dr. Vorwerk.—Take:—Pure carbolic acid, 45.0 grms.; camphor and oil of rosemary, each, 30 grms.; oil of cloves and aniline, each, 5 grms.; dissolve these substances in methylated spirits, 2.5 litres. Pure carbolic acid, 200 grms.; camphor, oil of cloves, oil of lemon-rind (*Ol. citri cort.*), nitrobenzol, each, 10 grms.; aniline, 2.5 grms.; dissolve in methylated spirits, 1.5 litres. These fluids are applied to the fabrics and furs by the aid of the so-called pulverisateurs, spray-producers. The operation if properly done will only be required to be repeated twice or, at most, three times a year. Since these mixtures are inflammable, the operation with the pulverisateur should only be performed by daylight. No goods nor colours are injured by exposure to the spray.

August, 1871.

This number contains the following papers relating to chemistry and collateral sciences:—

Action of the Water Air-Pump, its Application to Boiling, Evaporation, Distillation, Filtration in Vacuum, and for Drying Herbs and Crystals.—F. A. Wolff.—The contents of this valuable essay are not suited for abstraction, as it would involve the reproduction of a series of woodcuts.

Analysis of the Water of the "Karlsbrunnen," at Nauheim (Prussia, Hesse).—Dr. Uloth.—Sp. gr. of the water at 15° = 1.00895; 1000 grms. contain:—Carbonate of lime, 0.6608; carbonate of protoxide of iron, 0.010; carbonate of protoxide of manganese and of zinc, of each a trace; sulphate of strontia, 0.0087; sulphate of lime, 0.2277; chloride of ammonium, 0.0113; chloride of potassium, 0.0731; chloride of lithium, a trace; chloride of sodium, 0.3660; chloride of magnesium, 0.2040; chloride of calcium, 1.0578; bromide of magnesium, 0.0014; arsenite of protoxide of iron, a trace; phosphate of protoxide of iron, 0.002; silica, 0.0087; nitric acid and organic matter, of each a trace; sum of fixed salts, 12.1247; partly-combined carbonic acid, 0.2949.

Zeitschrift für Chemie von Beilstein, No. 10, 1871.

This number contains the following original papers and memoirs:—

Synthesis of Piperonylic Acid and New Mode of Formation of Protocatechu-Aldehyde.—R. Fittig and I. Reman.—After referring to some other researches bearing upon this subject, the authors state that they have made a mixture of 1 molecule of pure protocatechutic acid, 3 mols. of hydrate of potassa, and $\frac{1}{2}$ mols. of methylen-iodide, which has been put into a tube and, after sealing, the latter has been exposed for several hours to a temperature of 140°; the contents of the tube having been submitted to a lengthy and tedious process of purification yielded a methylen-protocatechutic acid which was found to be in physical as well as chemical properties identical with piperonylic acid. This experiment proves, therefore, that the acid just named is methylen-protocatechutic acid; as regards the constitution of piperic acid it is observed that it contains the group—

Ethylen-Protocatechutic Acid.—R. Fittig and T. Macalpine.—By causing protocatechutic acid, ethylen-bromide, and caustic potassa to react upon each other in a sealed tube, the authors obtained the ethylen-protocatechutic acid—

a body soluble in water and alcohol, very similar to piperonylic acid, fuses at 133°, sublimes at a higher temperature unaltered.

The Aldehyde of the Naphthalene Group.—J. Battersball.—The aldehyde of naphthol acid, $\text{C}_{11}\text{H}_7\text{O} = \text{C}_{11}\text{H}_7\text{CHO}$, is prepared by the distillation of a mixture of naphthoate of lime and formate of lime. The purified aldehyde is a colourless somewhat thickish fluid, heavier than water, boiling at 280°.

Benzol-Hexachloride.—Z. Heys.—The author has prepared this body, originally discovered many years ago by Prof. Mitscherlich, by

passing a current of chlorine into benzol for several days consecutively. The substance alluded to is solid, soluble in alcohol, crystalline, fuses at 157° . It appears that this hexachloride of benzol has very great stability, since it is not acted upon by boiling either with nitric or with nitro-sulphuric acids.

Action of Fusing Caustic Potassa upon Sulphoxybenzoic Acid.—I. Remsen.—This paper and the two following by the same author are written solely for the purpose of vindicating the correctness of his researches against the imputations published thereupon in other periodicals.

Isomeric Sulpho-Salicylic Acids.

Oxidation of Tolouol-Sulphuric Acids.

Researches on the Derivatives of β -Para-Brom-Sulpho-Tolouol.—F. C. G. Müller.—The amide of the ortho-tolouol-sulpho acid fuses at 92° , is crystalline, soluble in water. Nitro- β -para-brom-tolouol-sulpho acid is readily soluble in water, alcohol, and ether, crystalline, deliquescent; the acid and its salts are very bitter to the taste.

Nature of Sulpho- and Sulpho-Nitro-Bibrom-Benzol.—R. D. Williams.—The catalytic description of a series of salts belonging to sulpho-bibrom-benzol and bibrom-nitro-sulpho-benzol.

On Brom-Sulpho-Tolouol.—H. Hübner.—A short preliminary notice on this subject; a full account will be given hereafter.

Conversion of Allylic Alcohol into Acrylic Acid.—B. Tollens.—Pure bromide of allylic alcohol yields by oxidation an acid, $C_3H_3Br_2O_2$. This acid was treated with zinc-dust, and the result of that reaction again with sulphuric acid, whereby acrylic acid was obtained. The formation of acrylic acid from an acid, $C_3H_3Br_2O_2$, is akin to the formation of the first-named acid from propionic acid; it is also a proof which confirms the following formulæ:—

Action of Chloral upon Aniline.—O. Wallach.—Preliminary notice.

Electro-Thermo-Chemical Experiments.—Dr. E. Mulder and F. C. E. von Embden.—This excellent paper, being illustrated with woodcuts, does not admit of any useful abstraction.

New Edition of a Highly Valuable Work.—MM. Friedrich Vieweg and Son, at Brunswick, announce the publishing of a new edition of the well and deservedly known "Handwörterbuch der Chemie," under the title "Neues Handwörterbuch der Chemie," based upon that edited by Drs. Liebig, Wöhler, Poggendorff, Kolbe, and Fehling; the last-named of these *savants* is the editor of the new edition, with the co-operation of Drs. Bunsen, Fittig, Fresenius, v. Gorup-Besanez, Hofmann, Kekulé, Kolbe, Strecker, Wichelhaus, and others.

Les Mondes, September 28, 1871.

Exploration of the Baltic Sea.—Rev. F. Moigno.—The short and as yet preliminary account of a journey made by the Imperial German steamship *Pommern*, for the express purpose of making a thorough survey of the sea alluded to. It appears that the greatest depth, 240 metres, is met with between the island of Gothland and the Courland coast; notwithstanding it was in the middle of July, the temperature of the water at this depth was only from $0^{\circ}5'$ to 2° K. No marine plants were found at this depth, and animal life was only represented by two species of worms; the water at this depth and locality contains only a small quantity of salt in solution. At a less depth, 100 metres, there are animals living, and in the more shallow portions of this sea plants also vegetate.

Talpa Marina.—M. Toselli.—The description of some experiments made with a very ingenious contrivance, which may be briefly stated to be a greatly improved diving-bell, which has been tried at Baja, near Naples. This apparatus can accommodate two persons, has an air-vessel with strongly-compressed air attached for the requirements of respiration, telegraphic apparatus for communication with the shore or vessel from which the *talpa* is lowered under water, and an arrangement also by which, without being drawn up, the machine may reach the surface of the water and float.

Extraordinary Meteor Seen at Marseilles.—Dr. Coggia.—On August 1 last, at 10.43 p.m. Marseilles mean time ($5^{\circ}27'19''$ E. of London), the author observed a large blood-red coloured meteorite, which moved slowly in a direction first west and next north, having been lost sight of at $11^{\circ}3'28''$ p.m. The diameter (apparent) was about $15'$ at first, but decreased to $0.4'$. Before being lost sight of, this meteorite appeared to emit incandescent sparks.

Nomenclature of the Textile Fibres in Common Use.—Rev. F. Moigno.—Under this title the excellent *savant* calls attention to a scientific educational institute established at Melle-Lès-Gand, Belgium, which establishment, according to the few lines devoted to it here (the author recently paid it a visit), is one of the best arranged and most complete industrial-commercial schools to be met with anywhere, the museums, library, laboratories (chemical, physical, and mechanical), cosmographic, numismatic, and other collections being in every respect complete and up to the latest improvements and discoveries. It appears, further, that the teachers are not only men of high acquirements, but actively engaged in diffusing through the press useful knowledge, and part thereof is the publishing of the nomenclature of 550 plants utilisable for the purpose of rope, cordage, and paper-making, spinning, and weaving, &c.; to the name of each

plant (inclusive of those names in use in several Asiatic and other foreign dialects) are given all the synonyms, with every information required for travellers, naturalists, and parties connected with industry. The article here alluded to contains a specimen reproduction of this work, which is in the press.

La France Scientifique (Ancien Cosmos), September 24, 1871.

The editor of this periodical, Dr. V. Meunier, has chosen as motto for his new paper:—"Régénérer la France par la Science et la Science par la Liberté." We think, judging from the contents of this number, that the editor has taken a really sensible and correct view of matters, which it would be bad taste on our part to enter into details upon here, but which, if duly carried into practice, will certainly tend best to regenerate France, and, with the "Fluctuat nec Mergitur" of the ancient coat of arms of Paris borne in mind, we sincerely hope that millions of Frenchmen will acknowledge the correctness of the author's views, and firmly united together, bearing in mind the "Bene juncti valeamus pauci," achieve great things in the pursuits of peace (science, arts, industry, agriculture, and commerce), and make the Tricolour Français respected and esteemed all over the globe.

Le Moniteur des Produits Chimiques pour l'Industrie, les Sciences et les Arts et du Matériel de ces Industries Publié par une Société de Chimistes et d'Industriels, September 25, 1871.

Pigments and Dyes Known to and Used by the Ancients.—E. Rousset.—The continuation of this paper (see CHEMICAL NEWS, vol. xxiv., p. 134). It appears that the Ancients used the following yellow pigments:—Ochre, massicot, orpiment, and realgar; the latter are poisonous, and do not cover well; the former are devoid of any brilliancy. As to the yellow dyes used by the Ancients nothing is positively known, but it seems that woad, saffron, and other native plants were employed. Referring to yellow pigments discovered by modern chemistry, Naples yellow (antimoniate of lead), mineral yellow (oxychloride of lead), and the chromium colours, discovered by Vauquelin (1797), cadmium yellow, discovered by Stromeyer (1817), are mentioned. Among the modern yellow dyes, purrue and picric acid are enumerated. Vermillion, red ochres, and minium were known from a remote antiquity, though neither Greeks nor Romans were acquainted with the artificial preparation of vermilion, which has been known to the Chinese for a very lengthy series of centuries past. As to red dye-stuffs, there can be no doubt that madder was known and used not only for dyeing fabrics but also in the shape of so-called lake. Kermes, a dye-stuff little known in this country but yet used in France, was known to and used by the Ancients, being undoubtedly already used in Egypt *tempre* Moesa. Among the green paints the Ancients were only acquainted with some native green-coloured compounds of copper, and with the acetates of that metal; the number of green pigments discovered in modern times is very large, and need not be here alluded to. Of purple dyes known to and used by the Ancients, the celebrated Tyrian purple is here at length spoken of. Among the molluscs from which this dye was obtained is the *Janthina prolata*, yet found in the Mediterranean, and a very common object in that sea near Narbonne (in this very ancient city there were Tyrian purple dye-works at least 600 years B.C.), where in our days some experiments have been made by Dr. Leason which really prove that the mollusc just named yields, though only in very small quantity, an exceedingly beautiful purple. Dr. Bancroft was also acquainted with this fact, and made several trials for the purpose of ascertaining whether this dye-stuff might be again industrially applied.

Researches on Lydine.—P. Guyot.—A very beautiful violet colour known under the name just mentioned is prepared as follows:—Take 100 grms. of aniline, and dissolve it in 100 grms. of hydrochloric acid previously diluted with 120 c.c. of distilled water; pour this solution into a solution of red prussiate (ferricyanide of potassium) made of 90 grms. of the salt dissolved in 850 c.c. of water. The mixture is next boiled for an hour and a half, and then cooled.

Manufacture of Fatty Acids.—M. Bodisson.—The author has invented a process, not clearly described in this short notice—from which we only learn that a high temperature (300°) and a vacuum, at least exclusion of contact of air, are employed—by the application of which purer fatty acids and a greatly increased quantity (88 per cent from the tallow used) are obtained.

Polytechnisches Journal von Dingler, first number for September, 1871.

The following original papers relating to chemistry and collateral sciences are published in this number:—

Galvanic Battery (Tauch Batterie).—MM. Keiser and Schmidt.—The description of an improved galvanic battery, but requiring the aid of engravings for proper elucidation.

Continuation of the Essay on the Blast Furnaces.—C. Schinz.—The headings of the sections of this portion are—Capacity of furnace; economic conditions; means for saving fuel; use of coal as fuel.

Quantitative Estimation of Nitric Acid.—Dr. A. Wagner.—After briefly referring to a former communication on this subject (see CHEMICAL NEWS, vol. xxiii., p. 261), the author now describes another process, based upon the decomposition of the nitrate at a high temperature, and calculating from the quantity of deutoxide of nitrogen the amount of nitric acid. The experiment is carried on as follows:—In a combustion-tube of hard glass is placed, first $\frac{1}{2}$ gm. of bicarbonate of soda, next the mixture of nitrate of potassa (about $\frac{1}{2}$ a gm.) with chromic oxide and carbonate of soda. A gas conducting-tube is fastened by means of a perforated cork, the tube being placed in a furnace; that portion of it wherein the bicarbonate of soda is placed is first gently heated, so as to expel all air. The ignition to

bright redness of the portion of the tube containing the nitrate mixture is then proceeded with, and the gas collected in a graduated tube of at least 300 c.c. capacity, and standing in a mercury trough being partly filled with that metal, partly with a known quantity of a dilute titrated solution of caustic soda, while also 100 c.c. of pure oxygen occupy the upper part of the tube. The regenerated nitric acid is absorbed by the caustic soda, and this at the end of the operation titrated with dilute sulphuric acid. It is clear that an excess of oxygen is required, that the bicarbonate of soda has to be heated a second time to expel any remaining deutoxide of nitrogen, and that after the combustion has ceased the glass cylinder has to remain in the mercury trough for some time, and the contents of the cylinder gently shaken, so as to obtain a perfect reaction.

Estimation of the Non-Permanent Hardness of Water.—Dr. A. Wagner.—Reserved for full translation.

On some Applications of Sulphide of Carbon.—H. Haedicke.—This paper treats on the use of sulphide of carbon for the extraction of oils and fat by means of peculiarly-constructed apparatus, the arrangement of which is illustrated by engravings.

A Calorimeter.—H. Rbeineck.—Illustrated with a woodcut.

Influence Exerted by Secondary Extra Formation in Fermenting Wort.—Dr. W. Schulze.—This lengthy essay bears entirely upon the particular subjects of brewing and grain-spirit producing.

Annual Consumption of Beer per head of Population in the Undermentioned Countries.—Dr. Dingler.—Bavaria, 80 maasz (= 1069 litre each maasz); England, 74; Belgium, 51; Würtemberg, 40; Austria, 16; France, 13; Switzerland, 12; Prussia, 10. While 7.5 per cent of the entire revenue of the United Kingdom is derived from the beer (malt) tax, this amounts, for Bavaria, to 15.5 per cent; for Austria, 2.9 per cent; France, 1.9 per cent; Prussia, 1.2 per cent.

Journal für Gasbeleuchtung und Wasserversorgung, Nos. 17, 1871.

The contents of this number only bear upon subjects strictly relating to gas- and water-works' engineering and management.

La Revue des Scientifique de la France et de l'Etranger,
September 23, 1871.

This number does not contain any original papers relating to chemistry, but we call attention to the two following memoirs:—

Different Methods of Observation Employed in Stratigraphic Geology.—Dr. Bleicher.—An excellent essay, illustrated by several engravings.

Association of Commerce and Industry of Roubaix.—M. Féron.—Under the title just quoted, this paper contains an account of a lecture on the sorting of the impurities of wool, the means of cleansing that textile fibre, and on spinning, weaving, and dyeing it.

Biography of the Late E. Latet.—G. de Mortillet.—This paper records the labours and the published works of a celebrated geologist and paleontologist.

September 30, 1871.

This number does not contain any original papers strictly belonging to chemistry, but we quote the title of an excellent essay:—

Absorption of Gases by Organic Liquids.—Dr. Gréhaud.—Illustrated by a series of woodcuts. This essay is a portion of the author's published lectures on experimental physiology.

NOTES AND QUERIES.

Cement to Resist Sulphuric Acid.—(Reply to H. R. Yardley).—Take caoutchouc: melt this by a gentle heat, add from 6 to 8 per cent of the weight of tallow, taking care to keep the mass well stirred; add dry slaked lime, so as to make the fluid mass the consistency of soft paste; and, lastly, add 20 per cent of red lead, whereby the mass, which otherwise remains soft, becomes hard and dry. This cement resists, according to Dr. Wagner, boiling sulphuric acid. A solution of caoutchouc in twice its weight of raw linseed oil, aided by heating, and the addition thereto of an equal weight of pipeclay, yields a plastic mass which also resists most acids.

Electro-Deposition of Aluminium and other Metals.—I see it stated in your "Notes and Queries" that aluminium has not yet been deposited on other metals by the battery. For more than two years I have been depositing aluminium daily on iron, steel, and other metals, and driving it into their surfaces at a heat of about 500° F., in the same way as I do silver and nickel. Also I have been doing the same with the alloy of aluminium called aluminium bronze, of various tints, from the palest lemon to the richest gold colour. I also deposit occasionally platinum, but it would not stand on iron and steel if deposited from the solution named by your correspondent, nor, in fact, satisfactorily on any metal which is not neutral in that solution.—J. BAYNES THOMPSON, White Hall, Wraybury, Staines.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND Co., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c.: of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

North London School of Chemistry, Pharmacy, &c.

For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871—1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

The LATIN CLASS for the reading of Physicians' Prescriptions, Caesar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

THE CHEMICAL NEWS.

VOL. XXIV. No. 622.

A STUDY OF ALDEHYDE AND AMMONIUM COMBINATIONS.

By S. E. PHILLIPS.

Is there any evidence that certain hydrocarbons replace 2 atoms of hydrogen, others 3 atoms; and if so, would a tetra-atomic element or radical replace 4 atoms of H? I have looked with some amount of industry for many years at this problem, and now think that one of two things must subsist; either that the evidence is indeed very small, or such distinguished men as Berthollet and others, failing to see it, must have a vision distorted by preconceived hypothesis.

Admiring as I do the eminent abilities of the discoverer of sulph-urea, it is with much diffidence I moot, in regard to Mr. Reynolds's paper (CHEMICAL NEWS, vol. xxiv, p. 87) on this subject, that his point of view is contradicted, and his main object in altering the formulæ presumptive.

More than twenty years ago I discovered, or pointed out, the "atmonia" type, or the doubly condensed ammonia of which urea is an illustration. I then assumed that wherever (CO) existed, (CS) might be found to replace it, but chemists held that the sulph-urea had no existence, until Reynolds realised the fact in such a masterly way as to command universal acceptance.

I now maintain that not only two aldehyde radicals (which he seems to deny) but three or more atoms may be introduced into the atmonial type, and that the two primary ureas alluded to involve no particular speciality to separate them from the vast generic group to which they belong. As a moot point for enquiry, I jot down a few particulars from the slender means just now at command.

Professor Andrews, as President of the Chemical Section of the British Association, has called attention to a group which associates ethylen with other monatomic bodies in a way that may be instructive herein; and in a paper on the Amides, referring to the hydramides, I have sought to trace analogies between ethylen or aldehyde and other aldehydes or aromatic oils, which, with ammonia, give corresponding atmonias (ureas).

3 Almond oil,	3(C ₁₁ H ₁₆ O ₂) + H ₂ N - 6HO =	C ₃₃ H ₄₈	H ₃ N ₃
" Oil of anis,	"(C ₁₀ H ₁₄ O ₄) + "	"	(C ₁₀ H ₁₄ O ₂)H ₃ N ₂
" Cinnamon oil,	"(C ₁₅ H ₁₈ O ₂) + "	"	(C ₁₅ H ₁₇)H ₃ N ₂
" Aniseed oil,	"(C ₁₆ H ₂₀ O ₄) + "	"	(C ₁₆ H ₁₉ O ₂)H ₃ N ₂
" Acetone,	"(C ₆ H ₁₀ O ₂) + "	"	(C ₆ H ₈)H ₃ N ₂
" Aldehyde,	"(C ₄ H ₆ O ₂) + "	"	(?)

By oxidation, the radical constituents of these hydramides pass into their acid forms, furfurine gives pyromucic acid (C₁₀H₃O₂)O, which crystallises in a form like benzoic acid out of amarine, &c.

Acetonine is a colourless alkaline liquid of urinous odour, of which I give two saltic forms:—(C₆H₅)₃H₄N₂Cl + PtCl₂ and (C₆H₅)₃H₄N₂O + 2C₂O₃.

Carbo-thiacetonine is probably—

Baeyer's synthesis of picoline is instructive; 2 acrolein + ammonia = picoline—

M. Schiff's synthesis of coniine is still more so, as derived from the distillation of butyraldine—

Shröder gives us derivatives of valeraldehyde, thus:—

Density. Wt.

Valeraldine	= C ₁₀ H ₂₁ S ₁ N	144.5	289
Carbo-val-	= C ₂₂ H ₄₂ S ₁ N ₂	60.8	246
raldine			= (C ₁₀ H ₉) ₂ (CS) ₂ H ₃ N ₂ S + HS
Valeralde-	C ₁₀ H ₁₉ O ₂ N	52.16	103
hyde am-			= (C ₁₀ H ₉) ₂ H ₃ N ₂ O + HO
monia			

The analogy between acetone, carbo-thiacetonine, and carbo-valeraldine is close, and peradventure gives us the very substitution Reynolds assumes not to exist, and from which non-existence he deduces the alteration of type or structure. Divested of their saltic types they become—

Acetonine	(C ₆ H ₅) ₃	H ₃ N ₂
Carbo-thiacetonine	(C ₆ H ₅) ₃ (CS) ₂ H	N ₂
Carbo-valeraldine	(C ₁₀ H ₉) ₂ (CS) ₂ H ₂	N ₂
Aldehyde urea	(C ₄ H ₃)	(CS) ₂ H ₃ N ₂
	Original.	Altered.
Do. (Reynolds)	CS'' { NCH ₄ ''	{ NCH ₄ ''
	{ NH	{ CSH
		{ NH

It is no less amusing than instructive to compare these two forms with M. Schiff's notation of coniine—

I cannot understand what aldehyde-ammonia is, or thialdine, or the homologous 2-vol. valeraldin! If the 4 vols. rightly bespeaks a saltic type for carbo-valeraldine, then it may happen that the corresponding carbo-thialdine has been the very non-existent substance alluded to by Reynolds, viz.—

Carbo-valeraldine	(C ₁₀ H ₉) ₂ (CS) ₂ H ₃ N ₂ S + IIS
Carbo-thialdine	(C ₄ H ₃) ₂ (CS) ₂ H ₃ N ₂ S + HS
Sinapoline	(C ₆ H ₅) ₂ (CO) ₂ H ₂ N ₂
Thio-sinamin	(C ₆ H ₅) ₂ (CS) ₂ H ₃ N ₂

M. Arzruni gives some forms of sulph-ureas:—

(C ₁₄ H ₅ O ₂)	(CS) ₂ H ₃ N ₂
(C ₁₄ H ₅ O ₂) ₂	(CS) ₂ H ₂ N ₂
(C ₁₄ H ₅ O ₂) ₂	(CS) ₂ H ₂ N ₂

M. Schiff gives some atmonial forms with all the H constituents replaced—

Sal-hydr ethylanilide	(C ₁₂ H ₅) ₂ (C ₄ H ₅) ₂ (C ₁₄ H ₅ O ₂)H ₂ N ₂
Ethyl-sal-hydranilide	(C ₁₂ H ₅)(C ₄ H ₅)(C ₁₄ H ₅ O ₂)N
Ethyl-sal-hydr ethylanilide	(C ₁₂ H ₅) ₂ (C ₄ H ₅) ₂ (C ₁₄ H ₅ O ₂)N ₂
Copper sal-hydranilide	(C ₁₂ H ₅) ₂ (C ₄ H ₅ O ₂) ₂ Cu ₂ N ₂

It should be understood that I attach no particular value to the notations employed. I have simply followed Liebig and others in regard to well-established radicals in contradistinction to such as are now so rife in the multitudinous forms of modern notation. Sometimes I think the aromatic oils are hydrides, C₁₄H₅O₂H; at others they seem better regarded as of weak alcoholic types, C₁₄H₅O + HO. The ideas intended herein are probably both right, but with the ever-increasing knowledge of isomeric variation, it is most unwise to affect precision where all is shrouded in impenetrable darkness.

NOTES OF

DEMONSTRATIONS ON PHYSIOLOGICAL CHEMISTRY AT ST. GEORGE'S HOSPITAL.

By S. W. MOORE.

I.

ANIMAL tissues have 7ths of their weight as water; the percentage of ash varying, averaging 3.0 per cent. The elements in constitution of animals are about 17, some add Pb and As,—in all 19, viz., C, H, N, O, S, P, Cl, F, Ca, Mg, Al, K, Na, Fe, Mn, Cu, Si.

Metallic elements are best seen by spectroscopic demonstration after incineration of substance. The metals, with the exception of iron, are in the form of salts, as—

The elements occur in somewhat of the following order:—C, H, N, O, in most tissues; S in albumen; P in bone; Cl in juices as NaCl; in gastric juice as HCl; F and Si in teeth; the latter in bone also; Al, Ca, and Mg in teeth and bone; Na and K in blood; Fe in colouring matter of blood; Mn in hair; Cu in liver, bile, and gall-stones.

The non-metallic elements may be recognised as follows:—

C, by charring and formation of CO_2 when combusted; H, by formation of water; N, by heating with solid KHO and production of NH_3 ; S by combustion in pure KClO_3 is converted to K_2SO_4 , test with BaCl_2 ; P, by similar treatment, test with $\text{MgSO}_4 + \text{NH}_3$; Si by insolubility in acids; other elements are too indefinite to be recognised by simple testing.

These elements unite to form "proximate elements," which may be divided into two groups, nitrogenous and non-nitrogenous.

Albumen, with fibrin, casein, paralbumen, globulin, and vitellin, are the principle nitrogenous bodies, and have, according to Mulder, for their base a substance—protein, ($\text{C}_{18}\text{H}_{25}\text{N}_5\text{O}_5\text{H}_2\text{O}$)—which, he affirms, is free from sulphur, though hitherto it has not been so obtained.

It is worthy of remark that these compounds, which form the great bulk of our food, are richly charged with N. Albumen has a formula $\text{C}_{72}\text{H}_{112}\text{N}_{18}\text{SO}_{22}$, but in its soluble form is combined with Na, Gerhardt considering two atoms H displaceable, thus giving to white of egg the formula $\text{NaHC}_{72}\text{H}_{110}\text{N}_{18}\text{SO}_{22}\text{H}_2\text{O}$.

Soluble albumen is colourless, tasteless, glairy, and rotates to the left when polarised; evaporated at 50°C it becomes a yellow, brittle, transparent mass; this, washed successively with alcohol, ether, and hydrochloric acid, to remove extract, fat, and salts, is pure albumen. Albumen coagulates at 60°C . The mineral acids, except trihydric phosphate, precipitate albumen; the organic acids, except tannic acid, do not precipitate it.

Alum, HgCl , CuSO_4 , $\text{PbC}_2\text{H}_3\text{O}_2$, creasote, and alcohol, all precipitate albumen, but the most delicate test is potassic ferrocyanide in the presence of hydric acetate; HgCl detects 1-2000 in solution.

From the above data albumen is the best antidote for metallic salts when taken as poison. The S of albumen, during putrefaction, yields H_2S .

Protein is prepared by dissolving any albuminous body in KHO, and precipitating with hydric acetate. Hydric nitrate and protein produce xantho-proteic acid, a yellow inflammable body. Hydric chloride dissolves proteic compounds, producing a blue solution.

Protein and KHO, when boiled together, form carbonate and formate of ammonia, leucin, &c.; boiled with H_2SO_4 , leucin, tyroin, and other bodies are formed.

Albumen, boiled for some hours with water, is reduced to ammoniacal tritoxide of protein—

Paralbumen, globulin, myosin, &c., are modifications of albumen.

ON THE DETERMINATION OF SMALL QUANTITIES OF MANGANESE.

By THOMAS M. CHATARD.

THE delicacy of Crum's test for manganese is well known, but it is believed that no attempt has hitherto been made to employ it as a method of quantitative determination. The following work was, therefore, undertaken with that view.

A standard solution of ammonic oxalate was prepared, of which 1 c.c. = 0.0005467 grm. Mn. A sample of dolomite was taken, and four portions were weighed out. These were dissolved in nitric acid, and a small quantity of plumbic peroxide added to each. On boiling, the

bright colour of hypermanganic acid appeared. The solutions were passed through small filters of asbestos with the aid of a Bunsen's pump, and the hypermanganic acid was determined by means of a standard solution of ammonic oxalate, with the following results:—

Grm.	C.c.	Mn. Grm.	Mn. Per cent.
3.1300 dolomite required	39.0	0.0216	= 0.069
2.781 "	33.2	0.0181	= 0.065
2.0998 "	24.5	0.0134	= 0.063
1.8671 "	23.5	0.0128	= 0.062
Mean = 0.065 p. c. Mn.			

In a sample of limestone from White Horse, Chester Co., Pa. the analysis showed—

Grms.	C.c.	Mn. Grm.	Mn. Per cent.
3.4316 required	120	0.0656	= 1.92
2.2809 "	83.5	0.04564	= 2.00
4.0697 "	153.5	0.0838	= 2.05
Mean = 1.99 p. c. Mn.			

But the method, though giving good results, where the percentage of manganese is small, fails when any large amount of that metal is present. Well dried manganous pyrophosphate was treated with sulphuric acid, as nitric acid, though dissolving it was found not to decompose it, little or no hypermanganic acid being formed when the plumbic peroxide was added. With sulphuric acid, the red colour of hypermanganic acid was produced, but it was found that not even long boiling sufficed for total oxidation.

This was also the case with an alloy of iron and manganese. The longer it was boiled, the more hypermanganic acid was formed, but there seemed to be no definite limit. No concordant results having been reached, and a well marked end reaction in such cases being hard to obtain, the method as applied to general analysis was given up.

There seems to be, however, reason to maintain that when the quantity of manganese is very small, the method will be found both easy and accurate. Perhaps by some modification of the process, it may be made to apply also to the cases in which large quantities of manganese are present.

In conclusion, I desire to acknowledge my indebtedness to Dr. W. Gibbs for his careful supervision and many valuable suggestions.—*American Journal of Science*.

ON THE MICROSCOPICAL EXAMINATION OF DUST BLOWN INTO A RAILWAY CARRIAGE NEAR BIRMINGHAM.*

By JOSEPH SIDEBOTHAM, F.R.A.S.

ON the 24th May, 1870, while travelling by rail between Saltley and Camp Hill, I spread a paper on a seat of the carriage near the open window, and collected the dust that fell upon it. A rough examination of this with the two-thirds power showed a large proportion of fragments of iron, and on applying a soft iron needle I found that many of them were highly magnetic. They were mostly long, thin, and straight, the largest being about 1-150th of an inch, and, under the power used, had the appearance of a quantity of old nails. I then with a magnet separated the iron from the other particles.

The weight altogether of the dust collected was 5.7 grains, and the proportion of those particles composed wholly or in part of iron was 2.9 grains, or more than one-half. The iron thus separated consisted chiefly of fused particles of dross or burned iron, like "clinkers;" many were more or less spherical, like those brought to our notice

* Read before the Manchester Literary and Philosophical Society.

by Mr. Dancer from the flue of a furnace, but none so smooth; they were all more or less covered with spikes and excrescences, some having long tails like the old "Prince Rupert's" drops; there were also many small angular particles like cast-iron, having crystalline structure.

The other portion of the dust consisted largely of cinders, some very bright angular fragments of glass or quartz, a few bits of yellow metal, opaque white and spherical bodies, like those described by Mr. Dancer, grains of sand, a few bits of coal, &c.

After the examination of this dust, I could easily understand why it had produced such irritation; the number of angular, pointed, and spiked pieces of iron, and the scoria or clinkers, being quite sufficient to account for the unpleasant effect.

I think it probable that the magnetic strips of iron are laminæ from the rails and tires of the wheels, and the other iron particles portions of fused metal, either from the coal or from the furnace bars. The large proportion of iron found in the dust is probably owing to the metal being heavier than the ordinary dust, and accumulating in cuttings such as those between the two stations named.

If I had to travel much by railway through that district, I should like to wear magnetic railway spectacles, and a magnetic respirator in dry weather.

After the reading of the paper, Mr. CHARLES BAILEY drew attention to some experiments which Mr. Charles Stodder, of Boston, U.S., had been making on the microscopic contents of the atmosphere of that city. Amongst other investigations he was led to examine a fine black dust from a beam in the polishing shop of the United States Armoury, at Springfield. He found it to contain a few vegetable fibres, some apparently organic fragments, and some broken crystals; but the great mass of it was made up of amorphous fragments of iron, of the 1-100 m.m. and upwards in size, as well as curved and irregular fibres and masses of iron with sharp jagged edges, from 5 to 15 m.m. in size; there were also some very minute perfect spheres, probably iron. In trying the effect of the magnet upon this dust, he found it removed it from a sheet of paper as completely as if had been swept off with a brush, and he concluded that the non-metallic portions adhered to the iron particles by the thin layer of oil with which all the particles of dust were coated.

To prevent this dust passing into the atmosphere of cities, Mr. Stodder recommended a plan which had been put in practice many years ago in this country, but abandoned from the indifference of the workpeople, viz., the fixing of magnets in the immediate neighbourhood of grindstones and polishing wheels.

In the same report, Mr. Stodder alludes to the labours of two members of this Society—Dr. Angus Smith and Mr. J. B. Dancer—in examining the contents of the air, and points out an important matter considerably affecting the results of such investigations, viz., the method employed for filtering the air through water. The usual method has been to place a small quantity of pure water in a large bottle, and shake it in the air under investigations, repeating the operations with renewed volumes of air in the same water; but Mr. Stodder shows how impossible it is to intercept all the foreign particles in the atmosphere in this way, inasmuch as the smallest bubbles of air which pass through the water very much exceed in size the particles of matter which are sought for, and myriads must elude observation. A greater difficulty, however, is to obtain absolutely pure water for such experiments, and whether filtered or distilled water was used, a drop evaporated on a glass slide always left a deposit of scaly and granular particles. This result, as Mr. Stodder justly says, puts an end to this mode of investigation, and throws a cloud of suspicion on all reported researches in this line, when water was the medium used.

Mr. Bailey stated that the information communicated

above had been extracted from an official document emanating from the State Board of Health of Massachusetts, and he commended it to the Officers of Health and to the Corporations of Manchester and Salford, as an illustration of what is required in this neighbourhood. The document just issued gives a summary of the work done during the past year, and embraces reports upon Public Abattoirs; the Cattle Plague, and its Effect on Milk; an Outbreak of Typhoid Fever; the Overcrowding of Tenements and want of Clean Streets in Boston; Smallpox; Poisoning by Lead; Trichiniasis in Massachusetts; Health of the various Towns in the State; Homes for the People; Alcoholic Drinks; Mortality of the City of Boston; Ventilation of School-houses; Water Supply, and its Comparative Purity; Air, and some of its Impurities; Health of Children employed in the manufacture of Textile Fabrics; Effect of Sewing Machines on Health, &c., and all this at a cost of under £600 the year.

ON THE ADULTERATION OF FOOD,

PRINCIPALLY WITH A VIEW TO ITS DETECTION BY THE MICROSCOPE.*

By WALTER MORRIS.

ADULTERATION was defined as being the fraudulent addition to any substance of another, for the sake of increased sale or profit. There are several modes of accomplishing this end; the first, and the most common, is by the addition of some article to increase the bulk or weight, as when starch is added to mustard, and cheaper flours to wheat flour; the second by improving the appearance and apparent quality, so as to sell an inferior article at the price of a better, as in the case of the artificial colouring of pickles made of stale vegetables to resemble fresh. One of the commonest apologies for these practices is that the public prefer the adulterated article to the pure; that, for instance, pure mustard "will not sell." This allegation is, however, hardly a fair one, as the pure article is never offered; and, doubtless, if the pure article were used as freely as the ordinary mixture, it would be found unexpectedly pungent. But the fallacy of such apologies has been exposed by the example of pickles, which under this plea used to be invariably coloured with an artificial and frequently poisonous pigment. The public eye was thus educated to expect them of a bright green; yet, since some manufacturers have exposed the fraud and sent out pure pickles, the public have completely turned round, and avoid any which show an unnatural colour.

The adulteration of bread and flour with alum, to make them look whiter and of a superior quality, has to some extent diminished; but that substance is often replaced by the still worse sulphate of copper, or blue vitriol, which was recently detected in sixteen out of twenty loaves tested. In this case the public has been led to suppose that the quality of bread is shown by its whiteness, whereas by taking out the bran a most valuable part of the grain, viz., its azotised or flesh-forming portion, is lost. Less dangerous admixtures are those of cheaper flours, such as barley, rice, and "cones" (the latter made from a species of wheat called *revel*), and even beans.

The adulteration of coffee with chicory, though so well understood, exists, especially in poorer neighbourhoods, to an extent hardly credible. Out of forty-seven samples, eighteen were found pure, the lowest price of which was 1s. 4d. per lb.; of the rest, most were half, and some were wholly, composed of chicory, which, being worth about 6d. per lb., was thus sold at 1s. and 1s. 4d. The difference can be readily detected by the microscope, the cells of chicory being much larger, and the cell walls much thinner, than those of coffee.

* Abstract of a Paper read before the Manchester Literary and Philosophical Society.

Even chicory itself is much adulterated; out of fifty-seven samples only about one-half were pure, the adulterants being roasted wheat, acorns, beans, carrots, and sawdust.

Tea is less subject to adulteration than many articles of food; such abominations as the celebrated Maloo mixture, consisting of old used leaves re-dried, willow leaves and twigs, and even iron filings, have been quickly detected and refused by the trade. The "facing," however, of green tea with poisonous colouring matter is both absurd and harmful; and it will probably be continued so long as the public are content to accept such a palpable imposture as "genuine green."

It is a matter of opinion whether cocoa as ordinarily sold is to be considered an adulterated or a manufactured article. It is seldom sold pure and alone; being usually mixed with starch and sugar—the term "pure cocoa" is, therefore, in most cases, intended to mislead. Some kinds have lard or suet admixed, and to others red ochre is added to bring up the colour, rendered pale by an excessive quantity of starch. The relative quantities of these component parts in any sample of cocoa may be readily ascertained by the microscope; that of starch may be roughly seen by shaking up some of the cocoa with water in a test-tube or tall bottle, breaking up the lumps, and then allowing all to settle; when the starch will sink to the bottom and form a white layer beneath the cocoa. On warming the water, the fat will of course float on the top, and the sugar will be dissolved. The sugar crystals and fat are also shown by re-drying the solution on a glass slide.

Sugar is mixed with inferior kinds of the same article, but not (as popularly believed) with sand; the chief impurities in raw sugar are cane fibre, accidental dirt, and the sugar mite or acarus. The latter exists in most raw sugars (out of 72 samples 69 contained mites); but more abundantly in the moderately brown kinds than in the darker. The insect is barely visible to the naked eye. To obtain specimens, the sample should be dissolved in tepid water and well stirred, then allowed to stand a few minutes, and the acari will be found as minute particles floating on the top. The process of refining entirely removes these and the other impurities named.

Mustard is invariably adulterated with flour, which forms one-half or three-fourths of the article as usually sold. It may be readily detected by the microscope, mustard itself containing no starch whatever. Turmeric is often added to bring up the colour after this wholesale admixture, and cayenne to give it strength.

Pepper may now be obtained pure of respectable dealers; but as regards the cheaper kinds, and in poor neighbourhoods, it is largely adulterated with meal or starch, gypsum, and dirt of any kind, to give bulk and weight. The starchy substances may be detected by the microscope, the earthy ones will be left as ash after burning, and their character may be ascertained by the polariscope. The particles of pepper itself are easily recognised by the characteristic stellate cells in the outer skin, and the hard angular ones of the inner part of the seed.

Many examples of the above and other kinds of adulteration, mounted for the microscope, were exhibited at the same time, for comparison with pure specimens.

NOTE ON THE SPECTRUM OF THE CORONA.

By Professor C. A. YOUNG.

In an article upon the Solar Corona, which appeared in the *American Journal of Science*, May, 1871, I wrote, "Very perplexing also is the fact that the faint continuous spectrum, which must be in part produced by this polarised component of the corona's light, shows no discoverable traces of the dark lines of the ordinary sunlight spectrum.

Probably they exist, but are in some way masked so that they are not easily detected."

On further reflection, however, I believe the matter is readily explained, and that, on the other hand, it would have been remarkable if we had been able to bring out the Fraunhofer lines.

The truth is that the reflected photospheric sunlight forms only one small fraction of the total coronal radiance, the other constituents of which so far preponderate that it becomes very difficult to detect in the general spectrum the characteristics of this reflected light.

The spectrum of the corona is, in all probability, composed of at least four superposed elements.

1. A continuous spectrum, without lines either bright or dark, due to incandescent dust—that is, to particles of solid or liquid meteoric matter near the sun. For although I am not able to admit with Mr. Proctor that the whole explanation of the corona is involved in the presence of such meteoric particles, yet it cannot be doubted that they are very numerous; and any that may come within 250,000 miles of the solar surface must become incandescent and give such a spectrum as described.

2. A true gaseous spectrum of the second order, consisting, like all such spectra, of a more or less bright continuous background with well marked maxima or bright lines. In this case one bright line (1474) certainly exists, and perhaps several. So far as the spectroscopic evidence goes, this gas may be simply the vapour of the meteoric dust above alluded to, liberated by the heat of the sun, as when powdered sodium is dropped into an alcohol flame; or it may be disengaged for the instant from the same particles by electric discharges between them, as when the bright lines of metallic vapour appear in the spectrum of the spark produced by an induction coil. But in my previous article I have stated reasons for believing that the gas is of a more permanent character—a solar atmosphere through and in which the meteoric particles move as foreign bodies.

3. A true sunlight-spectrum (with its dark lines) formed by photospheric light reflected from the solar atmosphere and meteoric dust. To this reflected sunlight undoubtedly is due most of the polarisation, and were it possible to separate the polarised component of the coronal light from the rest, we might perhaps hope to find in it traces of the Fraunhofer lines. It is by no means impossible, however, that the spectroscopic character of reflected light may undergo some change, such as a partial obliteration or degradation of its lines, when the reflecting particles are sufficiently minute—small, that is as compared with the dimensions of a wave of light, so that they do not merely reflect the undulation at their surfaces, but themselves enter into motion bodily. Experiments upon the spectrum of the light emitted by one of the so-called actinic clouds, would, perhaps, clear up the subject.

4. Another component spectrum is due to the light reflected from the particles of our own atmosphere. This is a mixture of the three already named, with the addition of the chromosphere spectrum; for while at the middle of an eclipse the air is wholly shielded from photospheric sunlight, it is of course exposed to illumination from the prominences and upper portions of the chromosphere. This light from the terrestrial atmosphere, like that reflected by particles near the sun, is evidently partially polarised in radial planes.

And if there is between us and the moon at the moment of eclipse any cloud of cosmical dust, the light reflected by this would come in as *fifth* element. It would, however, only differ from that reflected by our own atmosphere by including a greater or less modicum of photospheric sunlight.

Furthermore, in instruments like those employed by Messrs. Abney and Pye, the chromosphere spectrum overlies that of the corona, and increases the complication.

It would seem, therefore, that only a small percentage

of the light which falls upon the slit of the spectroscope during a total eclipse contains the Fraunhofer lines at all, and it ought not to be considered strange that they are not readily observed.

In the same article I have stated that the photographs taken by the American party in Spain appear to differ essentially from those obtained by Mr. Brothers in Sicily.

This statement was based upon a comparison instituted by Mr. Lockyer, Professor Winlock, and myself, between a copy of the American photograph and a drawing* of Mr. Brothers's photograph, which (drawing) he had himself sent to Mr. Lockyer.

There was a general and even striking agreement between the two in respect to the position of the gaps and the distribution of the luminosity, yet there certainly were, as Mr. L. pointed out, very noticeable and important differences, and of a character to suggest that the extensive outside radiance might probably be of a less permanent character than the leucosphere, and of a different origin.

But I understand that when photographic copies of Mr. Brothers's and the American negatives are made to a common scale then these differences disappear, and the agreement becomes nearly absolute in respect to all essential particulars. If this be so, it certainly bears very strongly in favour of those theories which assign a purely solar origin to the whole phenomena.—*American Journal of Science.*

REPORT ON THE MOLECULAR DISSOCIATION BY HEAT OF COMPOUNDS IN SOLUTION.

By CHARLES R. C. TICHBORNE, F.C.S., M.R.I.A., &c.

PART I. Introduction.

M. DEVILLE's researches upon the dissociation of compounds by heat when converted into the gaseous condition, have brought prominently before us the antagonistic nature of thermal to chemical force.† We find that the antagonistic action of these forces is manifested when we are dealing with compounds in the liquid condition, or in the so-called solutions of solid substances. It is a commonly acknowledged idea that in such cases heat hastens and modifies chemical decompositions, but how it modifies them, and to what extent, are questions which are seldom clearly defined.

The main purport of this report is the application of such enquiries as those mentioned to the science of chemical geology. I may remark that some of the hypotheses mentioned in the course of my paper are generally acknowledged, some indirectly accepted, and some emanate from myself. Similar remarks will apply to the phenomena observed. To specify, or enter too fully into these niceties, would needlessly cumber my report with extraneous matter, and I have therefore determined to leave such points to the reader's discrimination, except in a few special cases.

We may have various phases of decomposition according to the force with which the molecular fragments of a compound are held together, and it is immaterial whether we consider such bodies as built up by the direct addition of molecules or by substitution. Compounds of a complex nature must be viewed as an aggregation of perfect entities, capable of having an individual existence, but these component molecules cannot be taken into account when we are considering the more complicated molecule, e.g., morphia splits up on the application of heat into

apomorphia and water. No one could for a moment suppose that the molecule H_2O existed as water in the morphia, as its removal radically changes all the properties of the resulting compound. The more complex molecule has peculiarities which are not common to its factors, and *vice versa*.

The importance of a study of such points in connection with chemical geology is almost self evident; but I may as well state that in this report the subject has been merely considered from a chemical point of view. The surface of the earth has been, and is, undergoing superficially a rapid change from its primitive condition of igneous construction. This change is continuously going on, and growing more and more profound. In this metamorphosis water may be considered as the prime mover towards the ultimate results of the chemical as well as the physical arrangement of our earth's surface. Such a line of study is as invaluable as it is difficult, and it will be my endeavour more to open up this line of research, than attempt to master even a moiety of such knowledge.

Compound molecules exist as solids, liquids, and gases, provided that the temperature necessary to convert them into these physical modifications is not above the temperature at which their components are dissociated. The application of heat to a molecule may be graphically, although perhaps rather fancifully, represented by Fig. 1.

FIG. 1.

	A	B
	Liquid.	Gaseous.
Solid.		

Now we can easily conceive that a substance A may be of sufficient structural stability to pass through all the increasing vibratory action without dissociation of its component molecules, until it has passed through the solid liquid, and far into the vaporous condition, whilst a substance B has what I will call a *thermanalytic point*, or the point where the equilibrium upon such a line is broken. If it lies between A or n, we have dissociation in the liquid condition. A great number of compounds are dissociated above the point B (e.g., anomalous vapour density of chloride of ammonium), whilst those dissociated between A and B are less common and are much less easy of observation.

Of course the following broad rules may be accepted. 1. The greater the temperature, the greater the number of molecules capable of dissociation, or the greater the tendency to dissociation. And on the contrary, the lower the temperature, the greater the molecular stability. 2. The more complicated the construction of the molecule, the lower the temperature at which dissociation commences; and after disruption, the higher the temperature necessary to carry on further dissociation of the residual molecule. 3. As a corollary, it follows that example of dissociation by heat in liquids, or of solids in solution, are comparatively uncommon, but that when such phenomena do occur, they materially affect ordinary reactions, and that, *ceteris paribus*, decompositions at one temperature will not of a necessity correspond with those effected at another temperature.

In aqueous solutions and at ordinary pressure all molecular dissociation must occur under 100° C., that is to say, within the boiling-point of the fluid in which the substance is dissolved. Under pressure, however, from the increased range of temperature, extraordinary phenomena may be induced, and thus heating in sealed tubes offers facilities for producing decompositions that cannot be brought about at ordinary temperatures.

Dissociation of compounds in solution, unless accompanied by some ocular demonstration, is apt to be overlooked, from the simple fact that the molecules rearrange themselves generally in the same form on cooling, and thus the change is transient. Frequently, however, both in mixtures and simple solutions, a dissociation is accom-

* I am not sure but we had a photographic copy of Mr. Brothers's drawing instead of the drawing itself; but we did not have a photographic copy of the original negative. No such copies had then been made.

† The modifications of force are for convenience considered in this paper as separate entities.

panied on cooling by a re-arrangement of the two or more groups of molecules according to the altered affinities. The statical condition having been once broken, a different arrangement may take place.

I may illustrate the phenomena to which I have referred in the introduction, by the consideration of a few of the most simple cases.

None are more common than dehydration. The molecules, H_2O , in such cases forming the crowning particles of complicated structures are held thereto with but a feeble force, and are easily dissevered even in solution. Lime-water is a familiar instance, and although it has not, that I am aware, been demonstrated, there can be little doubt that the precipitate got on boiling that fluid is due to dissociation of the molecule of water, or its dehydration, thus. The action of heat upon the hydrate of lime ($CaO \cdot H_2O$) is to produce CaO and H_2O , CaO being insoluble in water, or very much less soluble than its hydrate. The first is probably what takes place. The insolubility is, however, concurrent with the rise in temperature.

As there do not seem to be any experiments extant except the original ones of Dalton, this subject was considered sufficiently important to verify, as they bear upon an investigation to be ultimately embodied in this report.*

Experiment 1.

A saturated solution of lime was formed in the following manner:—

Freshly burned lime was slaked and washed by decantation (distilled water being used), the residual lime was then digested with fresh water for twenty-four hours, with occasional shaking. This, on subsidence, constituted the lime-water used. It is hardly necessary to observe that all this manipulation was carried on in a stoppered bottle. The bright lime-water was poured off into a flask; this was brought quickly to the boil, and whilst boiling poured upon a filter arranged in the following manner:—

A glass funnel was placed inside a double funnel of tin, the outer space of this double funnel being filled with glycerine, which was kept as near the boiling-point as practicable (the boiling-point of "Price's Glycerine" is about $177^\circ C.$ to 182°). By this means the lime-water is kept as near to the temperature of dissociation as possible during the whole of the draining and drying, which is only a matter of about half an hour. Hydrate of lime dried over sulphuric acid does not suffer loss on being submitted to a similar temperature. The precipitate was brushed into a platinum crucible and weighed; it was then ignited and the loss calculated.

In two determinations the weighings showed a considerable reduction, but in both cases this was much under the quantity required by a true hydrate.

Thus—

	Weight of precipitate.	Loss on ignition.	Percentage CaH_2O_2 .	
			Theory.	Practice.
1st determination ..	0.155 grms.	0.031	24.33	20.00
2nd ..	0.131 "	0.023	24.33	17.56

It is curious to observe that the second determination gives the amount of loss required by the formation of a

* The following quotations are taken from most of the recent authorities, and are all evidently based upon the original experiments of Dalton, published in 1810 ("A New System of Chemical Philosophy," part 11, by John Dalton, Manchester.) Dalton gives lime-water, formed at $60^\circ F.$, as containing one grain in 778 grms. of water, and at $212^\circ F.$, one grain in 1270. Watts's "Dictionary of Chemistry," vol. i, p. 718, says,—"Hydrate of lime is more soluble in cold than in hot water; hence, water saturated with lime, in the cold deposits the hydrate when boiled." Mitscherlich says, in his "Elements," part 2, p. 418, fourth edition, "Lime is soluble in about 700 parts of cold water. . . . If lime water saturated in the cold be raised to the boiling-point, half the lime is deposited." Wurtz in his "Dictionnaire de Chimie," quotes Dalton's experiments, and says, "La chaux est peu soluble dans l'eau et elle présente cette particularité qu'elle l'est plus à froid qu'à chaud," &c.

hydrate having the composition $3CaO \cdot 2H_2O$, viz., 17.64. This experiment was executed as rapidly as possible.

In the above determinations, the only point that was satisfactorily established, was the fact that a dehydration really does take place, and that the molecule H_2O is to a certain extent torn from its chemical position, even in the presence of an excess of water, and that it is not due to any specific insolubility of the hydrate at $100^\circ C.$

Experiments 2, 3, and 4, were to determine the solubility of lime at different temperatures. Chemically pure carbonate of calcium was prepared by dissolving the precipitated commercial preparation in hydrochloric acid, and by treating the resulting solution with sulphide of hydrogen and filtering. The filtrate was then allowed to digest with a slight quantity of ammonia, and again filtered after warming. A few drops of sulphuric acid were added, and it was allowed to stand twenty-four hours before filtering from the precipitated sulphates. From this solution the carbonate was prepared with the aid of carbonate of ammonium. The well-washed carbonate was ignited in a platinum crucible, until it no longer effervesced on the addition of dilute hydrochloric acid. Having procured what might be considered as pure lime, the next point was to determine its solubility at different temperatures in the following manner.

Expt. 2.—Determination of the Solubility at $15.5^\circ C.$

After standing upon an excess of lime for some days in a silver flask, a lime-water was procured by decantation. For twelve hours before pouring off it was rigorously maintained at a temperature of $15.5^\circ C.$ 4000 grain measures were operated upon in each determination. In the two last determinations the lime-water was filtered in an apparatus by which as much as possible of the atmospheric carbonic anhydride was excluded. I am of opinion that these last determinations give the results as a little under the mark, but I am also of opinion that decantation probably gives it over; for these reasons the average of the three experiments have been taken. The estimation was made with a volumetric solution of sulphuric acid, 100 degrees of which would neutralise one equivalent of monovalent element.

		Degree of vol. solution.
1st determination (decanted) ..	..	20
2nd .. (filtered) ..	..	19
3rd .. " ..	..	18.9

Therefore, as $19.3 \frac{CaO}{200} = 5.405$ grains of lime present in 4005, so 1 grain of lime, or its equivalent of hydrate, requires 741 grains of water at $15.5^\circ C.$

Expt. 3.—Determination of the Solubility of Lime at $100^\circ C.$

A small copper boiler was used in this experiment which was provided with a valve to regulate the pressure, and a thermometer to indicate the temperature in the interior.

Through the top of this boiler passed what may be described as a kind of "Beal's filter." It consisted of a glass tube bent at right angles, one of the ends of this tube being moulded into a bell-shaped mouth, which mouth was tied over with a piece of Swedish filtering paper, and over this again a piece of muslin, which might be also placed upon the other side if great pressure were going to be used. By this arrangement, although the orifice presented a perfect filtering medium, it would stand a considerable amount of pressure. This end was submerged about half way into the boiler, which was filled with pure lime-water procured as in the previous experiment. The other end of the tube was provided with a glass stop-cock. The stop-cock was closed, and the lime-water rapidly brought to the boil. On allowing the valve to exert a slight pressure in the interior, and opening the stop-cock slightly, the lime-water slowly flowed out, the

pressure in the interior being just sufficient to force the lime-water through the bibulous paper, and up the capillary tube. The thermometer would occasionally go up a degree, but this was at once remedied by opening the valve. When a sufficient quantity of water had been collected in this manner the amount of lime was estimated as in the previous experiment.

In two determinations 3002 grains consumed 8 degrees of the vol. solution $8 \frac{\text{CaO}}{200} = 2.24$ grains lime present, or 1 in 1340.

Expt. 4.—Determination of Solubility at 109° C.

This experiment was performed in exactly a similar manner to the previous one, except that the valve was so placed that it blew off at a pressure corresponding to a temperature of 109° C. 3000 grains obtained in this manner consumed six degrees of the volumetric solution of acid, $6 \frac{\text{CaO}}{200} = 1.68$ grains of lime in solution.

These results may be tabulated as follows:—

One part of water at	Takes up of CaO.
15.5° C.	1.17
100° C.	1.845
109° C.	1.775

and so on, until a point would be reached at which lime would practically be insoluble.*

The dissociation of water from lime seems peculiar to many of its compounds, and seems connected with the dimorphism of carbonate of calcium (see "Calcite and Arragonite.")

The determination of the solubility of lime at different temperatures are of importance in connection with this report, because, independently of its geological bearing, it affords a simple but illustrative example of the dissociation of compounds generally when in solution.

In this example we have the combined molecule H₂O becoming separated in the presence of an overwhelming excess of water from the dissociative influence of heat.

The gradual character of the action is also strikingly illustrated, the dissociation being in ratio to the increment of temperature, and is, under ordinary circumstances, only stopped by having arrived at the maximum temperature of water at the pressure of the atmosphere.

The phenomenon, however, is capable of further extension under increased pressure *ad infinitum*. The laws of molecular dissociation by heat have been only studied as far as regards volatile substances, but these laws seem applicable to the solution of substances modified by the altered physical condition, and are in their phenomena very similar. Thus, in speaking of gaseous dissociation in connection with the laws of Avogadro and Ampère, M. Wurtz makes the following remarks:—

"Un des meilleurs arguments qu'on puisse invoquer en faveur de cette interprétation est celui qui est tiré de la densité du vapeur du bromhydrate d'amylène. C'est une combinaison liquide du carbure d'hydrogène d'amylène

avec l'acide bromhydrique. Portée à une température peu supérieure à son point d'ébullition cette combinaison montre une densité de vapeur qu'on peut appeler normale, parce qu'elle répond à 2 volumes de vapeur pour 1 molécule. La vapeur est intacte à cette température, mais dès qu'on la chauffe, elle va éprouver une décomposition plus ou moins complète, suivant que la chaleur fournie aura été plus ou moins considérable. . . . Mais cette décomposition est graduelle; elle ne s'achève pas à un degré fixe, mais entre des limites de température assez étendues, de telle sorte que la vapeur, intacte à un certain degré, se trouve mélangée, à des degrés plus élevés, avec des portions de plus en plus notable de ses produits de décomposition, jusqu'à ce qu'enfin la température s'étant élevée encore, la décomposition se trouve achevée. A ce moment, la densité de vapeur est descendue à la moitié de ce qu'elle était d'abord. Peut-on en conclure que le bromhydrate d'amylène offre deux densités de vapeur? Il est évident qu'il ne saurait en être ainsi, et il est naturel de penser que la vraie densité de vapeur est celle qui a été déterminée à une température assez basse pour qu'on soit en droit de supposer que la molécule est encore intacte. Que si cette densité décroît avec la température, cette circonstance est due à l'action de décomposition que la chaleur exerce sur la vapeur."

Again, in speaking of the exceptions to the laws of Avogadro and Ampère, he says—"Deux molécules, capables de prendre chacune la forme gazeuse, sont remises par l'affinité en une molécule plus complexe. Il peut se faire que le point d'ébullition de celle-ci soit situé assez bas pour que la chaleur qu'elles avaient perdue en s'unissant; elles demeurent alors en combinaison. Mais peut-on s'attendre à ce qu'il en soit toujours ainsi? E l'affinité de deux corps l'un pour l'autre ne peut elle pas être assez faible, ou le composé qu'ils forment assez peu volatil pour que le point de décomposition soit situé au dessous du point d'ébullition?"

Substances in solution must behave in a similar manner to those in a gaseous condition, except that in such cases it is only the more loosely combined molecules that are effected at ordinary pressure, but still we cannot conceive that there could be any limit to this decomposition under extraordinary pressure such as would be exerted frequently, subterraneously.

We know that compound structures are capable of being separated piecemeal—e.g., a compound of alum. The molecules are removable, commencing with the water of crystallisation, and ending with its most ultimate molecules. Thus, let us take the trimethylamine alum† a well defined compound, exactly similar in general construction to ordinary alums (C₃H₁₁N, Al^{III}; 2SO₄.12H₂O). We see at once the great number of molecular points of dissociation it is capable of being divided into, beginning with the first 10 molecules of H₂O that, according to Gerhardt, are removable at 120° C. or ending with—

Hertwig says the molecules H₂O are removable in three instalments. How far the action of heat is capable of splitting up this structure when in solution resolves itself into a question of pressure, but it will be seen further on that on the application of heat to such a compound as an alum, it reacts upon all the more unstable parts exactly as if they were not grouped together in the first instance, and that the whole structure is, if anything, lowered as regards its thermanalytic point, and thus weakened by its complexity. As the components are removed the residue has more stability.

The molecules known under the terms "water of crystallisation" are but slightly removed from the water of "hydration," and but slightly removed from the water of

* Dalton's experiments upon this subject are in his "New System of Chemical Philosophy," Part 2; Manchester, 1810. They are as follows:—When water of 60° is duly agitated with hydrate of lime, it clears slowly, but a quantity of lime-water may soon be passed through a filter of blotting-paper, when it becomes clear and fit for use. 1 found 7000 grains of this water required 75 grains of test sulphuric acid for its saturation, consequently it contained 9 grains of lime. If a quantity of this saturated water, mixed with hydrate of lime, be warmed to 130° and then agitated, it soon becomes clear; 7000 grains of this water decanted require only 60 grains of test sulphuric acid. The same time-water was boiled with hydrate of lime for two or three minutes and set aside to cool without agitation; it very soon cleared. 7000 grains being decanted require only 46 grains of test sulphuric acid to be neutralised, the test acid being as usual 1.134. Hence we deduce the following table:—

One part of water at	Takes up of lime:	Hydrate of lime:
60° F.	1.778	1.584
130° F.	1.972	1.729
212° F.	1.1270	1.252

† "Histoire des Doctrines Chimique," par Ad. Wurtz, p. 79.

† There being no practical line of demarcation between what is known as "organic substances" and "inorganic substances" as regards the laws of dissociation, examples taken from organic chemistry are *en rapport* with the objects of the paper.

solution; frequently the alteration of a few degrees of temperature are sufficient to convert one into the other, *e. g.*, sulphate of sodium and salts that dissolve in their own water of crystallisation.

The water in the salt seems to be in a crystalloidal condition, but as a colloid in the other case. The crystalloidal water, even in solution, frequently is capable of dissociation, and of apparently changing its condition. Such changes produce the phenomena of supersaturated solutions.

The phenomenon of solution is a demonstration of force and of actual combination between the molecules of water and the substance dissolved. But if the more intimate unions be taken, it is evident that in such cases as hydration or water of crystallisation the molecules that we recognise as H_2O are playing different formations, or are in a different condition to the water of solution.

In an octahedron crystal of ammonia-alum water is almost essentially the geometrical solid, and is as important as the alumina, ammonia, or other elements.

If this alum be dissolved by applying heat, it is split up into a substance which is no longer alum geometrically or chemically, although we have got conventionally into the habit of saying it has "dissolved in water," or it has "dissolved in its water of crystallisation," as the case may be. It is not only decomposed, but requires some little time for the molecules of water to regain their accustomed position or crystalloidal condition—so that they may be assimilated into the edifice—as illustrated by the following.

Experiment 5.

A saturated solution of the ammonia ferric alum was poured upon a small quantity of the crystals of the same salt, and a few drops of acid added to prevent the precipitation of a basic salt. It was quickly brought to the boil, and then allowed to remain at rest until it had regained the original temperature, $15^{\circ}C$. Although the solution had a thermometer frequently inserted and withdrawn, there was no indication of crystallisation until some three to four hours had elapsed. Now, under the ordinary rules of solubility these crystals should begin to form immediately that the thermometer reached $15^{\circ}C$. This phenomenon is exhibited by all the hydrated soluble salts in some degree; it is particularly the case with the alums.

A very interesting and remarkable group of molecules are the basylous trioxides—of which, however, we need only consider three. These three bases are Al_2O_3 , Cr_2O_3 , and Fe_2O_3 , oxides which perform a very important part in our earth's crust, and possess well-known properties in common. The first and last alumina and ferric oxide are, perhaps, the most important of the mineral world, if we except silicon and lime. There is a wonderful analogy between all their compounds, and they all possess in common a less degree of molecular stability from complexity of construction, and *ergo* a corresponding susceptibility to the action of heat when in solution.

M. Debray has lately published some ingenious observations upon the action of heat upon one of these solutions, namely, the ferric salts.* As my own experiments, however, have led to rather different results, I have simply given my own experience, and feel less delicacy in doing so from the fact that my investigations in this direction were well known, and have a prior date to those of M. Debray. I exhibited some experiments upon the dissociating influence of heat on these solutions before the Dublin Chemical Club in 1867.†

This dissociation is well marked in the ferric salts by the colour of their solutions. All the ferric salts are nearly colourless, or possess a very faint lemon tinge. It is probable that if we could get the tri-salt in solution without decomposition, a perfectly colourless liquid would be the result.

Experiment 6.

Ferric chloride, obtained by passing chlorine over iron filings heated in a porcelain tube, was dissolved in a moderate quantity of pure water (free from ammonia). A dilute solution of hydrochloric acid was then added, drop by drop, until the minimum point of colouration had been obtained. The iron was then estimated by precipitation with ammonia, and the chlorine by nitrate of silver.

The following figures represent the results obtained:—

	Practice.	Theory, per cent.
Fe	33.91	34.46
Cl	66.09	65.54

This slight increase in the amount of chlorine is evidently due to the basylous action of the water, and chromatic neutrality of such salts is dependent upon the amount of dilution, and is, in a certain sense, independent of the chemical neutrality. A chemically pure salt when dissolved gives a slightly basic solution, depending upon the relative volume of the water it is dissolved in.

Experiment 7.

The further addition of acid produced a darkening of the solution which had previously been rendered as neutral as practicable. Therefore, both acidity and basicity produce colours in these solutions.

Heat applied to these solutions gives an intense darkening in ratio to the temperature employed. It is almost certain, as will be seen from the experiments detailed, that the first action of the heat is the dissociation of crystalloidal water, and then the splitting up of the structure into a basic salt and free hydrochloric acid; and that the dissociation may be carried ultimately so far as results in the total splitting up of the structure. These results do not, however, agree with M. Debray's conclusions. Presuming that there is no other disturbing cause, the molecules regain their original arrangement of structure on cooling; but time becomes an important element here, the time required being in ratio to the extent of dissociation. The preparation of the ferric salts used was effected in the following manner:—

A neutral persulphate was formed in the moist way, preference being given to this method to that first adopted, namely, that of making the chloride obtained by sublimation the starting-point.

To a weighed quantity of ferrous sulphate dissolved in water the requisite proportions of nitric and sulphuric acids were added by the aid of volumetric solutions, carefully adjusted. The salt was evaporated to dryness at about $80^{\circ}C$., and after powdering was kept for some days at a temperature of about $75^{\circ}C$. This powder when thrown into water slowly dissolved in the cold, giving a slightly tinged and basic solution, which required the cautious addition of weak sulphuric acid. The addition of chloride of barium to this salt in equivalent proportions gave also a neutral solution of ferric chloride, &c.

Experiment 8.

A concentrated solution of ferric sulphate was submitted to a temperature of $100^{\circ}C$., the solution gradually became darker during the increment of heat. But there was no evidence of precipitation.

Experiment 9.

The above solution was rather copiously diluted, and on being re-heated it gave a basic precipitate of a yellow character, which contained sulphuric acid. Placed under the microscope it was seen to consist of semi-transparent and crystalline masses. By long and continued boiling a precipitate was procured in a more concentrated solution.

Experiment 10.

The basic precipitate procured in the above experiment was sealed up in a tube with the liquid in which it was formed, and occasionally agitated. After the lapse of some

* *Comptes Rendus*, April, 1869.

† *Minutes of the Dublin Chemical and Philosophical Club*, 1867.

considerable time it re-dissolved, with the formation of the original salt. To ensure success it is necessary that the boiling in the first instance should not be carried too far, and that the fluid be not too much diluted. A similar tube tied upon the beam of a steam-engine to ensure constant and energetic agitation gave the same results in two days.

(To be continued).

CORRESPONDENCE.

VITALITY OF DISEASE GERMS.

To the Editor of the Chemical News.

SIR,—Allow me, in reply to a letter which has appeared in the *CHEMICAL NEWS* of the 20th inst., signed H. B. Yardley, to state that if that gentleman will kindly refer to my paper on the "Action of Heat on Germ Life Dried on Cotton Fabrics," which appeared in the *CHEMICAL NEWS* of September 22, he will find at page 138 an answer to the question he asks.

If there is still vibrio life at 300°, and the calico is rendered tender at that temperature, I cannot see what further light would be thrown on the subject by repeating the experiment at 330° as suggested by him.

Permit me to trespass further on your space by alluding to a serious omission which occurred in the printing of my paper on the "Estimation of Sulphur in Coal and Coke," published in your issue of 18th August last. The sentence as printed reads—"The finely pulverised coal or coke is boiled for about twenty hours with water containing an equal weight of coal or coke taken. It should have been—"The finely pulverised coal or coke is boiled for about twenty hours with water containing an equal weight of carbonate of soda with that of the coal or coke taken.—I am, &c.,

F. CRACE CALVERT.

Royal Institution, Manchester,

VITALITY OF DISEASE GERMS.

To the Editor of the Chemical News.

SIR,—The recent experiments of Dr. F. Crace Calvert "On the Action of Heat on Protoplasmic Life" published in this journal have confirmed my suspicions, that an ordinary amount of heat is not sufficient to destroy the virus of contagion, but I will make this proviso, in the absence of disinfecting agents.

I have devoted a considerable portion of time to the study of disinfectants—in fact, sanitary chemistry generally, and the fact struck me as soon as I entered the field that the miasm was not destroyed by the heat of most disinfecting chambers. In fact, in some, where the heat employed is very low, owing to a badly constructed oven, very little good can accrue from the baking process alone. At the Sanatorium attached to Eton College the beds from the scarlatina patients used to be baked at rather a high temperature, but owing to scorplings having taken place the temperature has been considerably reduced. The heat now employed, if used alone, is, in my opinion, only just enough to warm the disease germ and make it feel very comfortable. The heat cannot be raised too high owing to its irregular working, the temperature being sometimes 40 or 50 degrees higher than the thermometer indicates. In December, 1870, I found the heat was only got up to 120° F., but it was supposed to rise to 160° F. I gave as my opinion that the heat had very little action upon the disease germ, and proposed placing a vessel containing carbolic acid mixed with an equal volume of water in the hot chamber. I have now, since the appearance of Mr. R. Weaver's letter (*CHEMICAL NEWS*, vol. xxiv., p. 166), written to know whether the system proposed by me has been fully carried out. I find that for the last nine months,

when articles have been placed in the disinfecting chamber, the heat has been averaging from 120° F. to 160° F., and a vessel of dilute carbolic acid (1 to 1) has been placed in the next compartment to the clothes. The vapour of the phenol has been carried over by the combined effects of heat and steam, and has saturated the clothing. This I consider a good method, certainly better than baking alone, for insuring complete destruction of any lower organism.

Previous to December, 1870, the method of disinfecting the patients' linen before washing, was to steep in solution of bleaching-powder, but owing to the solution being sometimes made improperly, holes were burnt in the clothing; I thereupon proposed a dilute solution of carbolic acid; it is easy to mix, perfectly soluble, and has no action upon fabrics in the diluted state.

I have just penned these few remarks as I hold the subject as one of the highest importance, and hoping it will raise a discussion in order to bring forth fresh facts.—I am, &c.,

GEORGE E. DAVIS.

Laboratory, R. Bealey and Co., Radcliffe.

THE BESSEMER PROCESS.

To the Editor of the Chemical News.

SIR,—I have read with much interest the many excellent articles on the Bessemer process, which have of late appeared in the *CHEMICAL NEWS*. They convey much valuable information, but I cannot help thinking the well-known fact that the grey iron used for the Bessemer process is converted into white during the first period of the blow should have been noticed, more especially as the full carbon spectrum (from all I can gather) is not seen until this change has been effected.

Mr. Snelus's own analyses, also those of others, show that the graphite (in the grey iron) is gradually occluded or dissolved in the iron, and that the boil does not fairly commence until the change is complete. It is well-known the same change occurs in the refinery and puddling furnaces. In the latter I have noticed the boil does not commence until this point has been attained.

In many instances grey iron is passed through the refinery for this object alone, thereby greatly facilitating and shortening its subsequent puddling.

Further, I think it doubtful that graphite (as such) is burnt at all in the converter; it may be that it is unaffected by the blast, and is only oxidised after entering into combination with the iron.

I have one question to ask, to which I should like a reply from some of your correspondents whose chemical knowledge must, of necessity, be superior to mine. During the conversion of grey pig-iron into white as above, is there a decrease or increase of temperature in the fluid blown iron due to this cause alone? I have thought it probable the latter may occur.—I am, &c.

JOHN PARRY.

Ebbw Vale Iron Works, Monmouthshire.

THE AMMONIA PROCESS OF WATER ANALYSIS.

To the Editor of the Chemical News.

My attention has been called to a letter from Mr. Edward Nicholson, Assistant Surgeon R.A., Analyst of Waters Mysore and Ceder Districts, dated 18th August, 1871, and written in Bangalore. It was published in the *CHEMICAL NEWS* of the 13th inst.

In this letter Mr. Nicholson confirms my statement, that our ammonia process had been adopted by the sanitary officers of the Indian Government. He, however, gives his opinion that it was adopted rather too hastily, and says that in his own hands it has been a complete failure. I have to thank him for not resting satisfied with a summary condemnation of our process, and for recording

the reasons why he condemns it. Among these reasons I observe that, in his hands, water to which quinine had been added failed to yield ammonia when subjected to our process. In answer, I beg leave to refer to some experiments published by Chapman and myself in the *Journal of the Chemical Society*, in the year 1868 (ser. 2, vol. vi., p. 165). From 100 parts of sulphate of quinine we obtained 4.5 parts of ammonia. Frankland and Armstrong have likewise published a determination of the amount of ammonia given by sulphate of quinine when it is submitted to the ammonia process, and even they so far agree with us as to exhibit a considerable yield of ammonia, viz., 3.64 per cent.

If any of your readers should be disposed to distrust the ammonia process on account of Mr. Nicholson's assertions respecting the working of it, I would recommend them to experiment on quinine before doing so.

Inasmuch as Mr. Nicholson failed to get ammonia from quinine, I am not surprised at his failing, in a general way, to obtain albumenoid ammonia from the waters of India, but I should hesitate to regard his failure to get ammonia as any reason for believing that it is not to be got when the ammonia process is efficiently worked.—I am, &c.,

J. ALFRED WANKLYN.

ELEMENTS, COMPOUNDS, AND MIXTURES.

To the Editor of the Chemical News.

SIR,—It is the general teaching of works on chemistry that matter is divisible into two classes, *elements* and *compounds*. Is this teaching true? I incline to the opinion that it is not, one reason for which I will proceed to state. Let us admit, for the sake of argument, that the teaching is true, and then proceed to the examination of one of the most common substances—*atmospheric air*. Before commencing to experiment upon the atmosphere, we can at once say it is either an element or a compound. On making our examination, however, we find that it is not the former, for it consists of two elements—oxygen and nitrogen, and two compounds—water vapour, and carbonic anhydride; neither is it the latter, for these elements and compounds are not held together by chemical attraction, which is characteristic of a compound. Now, since it belongs to neither of these classes, we must conclude that there are *three* classes of substances—elements, compounds, and mixtures—and that of this third class the atmosphere is a mixture and that.

I shall be glad to see the matter discussed in the columns of the CHEMICAL NEWS, so that the indefiniteness which at present prevails in the teaching on this point—to my mind at least—may be cleared up.—I am, &c.,

W. H. WOOD.

Halifax, Oct. 24, 1871.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 2, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Variable Aspect of the Protuberances and other Remarkable Portions Visible on the Sun's Surface; Classification of the Phenomena.—Rev. A. Secchi, S.J.—This very elaborate memoir is illustrated by a series of engravings.

Researches on the Reciprocal Conversion of the Allotropic States of Phosphorus.—(Second part.)—G. Lemoine.—It is not possible, owing to the great length of this memoir and to the fact that it contains a great many tabulated forms exhibiting results of experiments, to enter into details on the subject. The main results of the author's researches, while to some extent confirming the results of a very limited number of experiments made on this subject in 1865 by Dr. Hittorf (*Pogg. Ann.*, vol. cxvii.), prove that the conversion of phosphorus is chiefly a phenomenon of tension of vapours.

Estimation of the Velocity of Light.—A. Cornu.

Spectra of Tin and its Compounds.—G. Salet.—The exhaustive description of the spectrum phenomena observed when tin compounds are volatilised in the flame of hydrogen. It appears that tin in this respect is a most curious substance, since its compounds yield each three different spectra, two of which belong to all, while the third spectrum is continuous.

Continuation of the Thermo-Chemical Researches on the Ammoniacal Salts.—Dr. Berthelot.

Composition of the Clays Belonging to the Coal Formation.—C. Mène.—In tabulated form the author exhibits the results of the analysis of thirty-seven different kinds of this clay as obtained in France, Belgium, England, and Germany. The determinations made are:—Water, lime, silica, alumina, oxides of iron, alkalies, carbonaceous matter, and sp. gr. The contents of this paper are valuable, but do not admit of reproduction.

Loss of Valuable Libraries.—From a short note we learn that the Préfet de la Seine and the Préfet de Police request the Academy to have the kindness to send any books it might be able to dispose of to the two authorities just named, the former asking for the once magnificent municipal library of Paris, and the latter for the once very good library of the Prefecture, both of which have been destroyed by fire during the late war.

Annalen der Chemie und Pharmacie, September, 1871.

The following original memoirs and papers are contained in this number:—

Studies on the Combinations of the Camphor Group.—J. Kachler.—The first instalment of an exhaustive essay on this subject, containing the following sections:—Oxidation of camphor; nitrocamphoric acid; acids obtained from the mother-liquor; bibasic salts; tribasic salts; oxicamphoric acid.

Protein Compounds.—(First portion of essay.)—H. Hissjwetz and J. Habermann.—This paper contains an exhaustive general introduction to this subject, setting forth a comparison between the carbohydrates and the protein compounds, as regards the products yielded by the action of various reagents and decomposition-inducing processes, such as, for instance, fermentation, nitric acid, action of nascent oxygen, sulphuric acid, fusing caustic potassa, and dry distillation. Next follows the detailed account of a series of experiments made with the view to ascertain with certainty the derivatives or decomposition-products of carbohydrates among the products of the decomposition of the protein compounds.

Allantoine and its Derivatives.—Dr. E. Mulder.—This very exhaustive and lengthy memoir is divided into the following sections:—Preparation of allantoine according to Liebig's and Wöhler's method; nitrate of allantoine, $C_4H_8N_4O_3 \cdot NO_2 \cdot H_2O$; allanic acid, $C_4H_8N_4O_3$; allanturic acid, $C_4H_6N_4O_3$; allantoic acid, $C_4H_8N_4O_3$; lantanuric acid, $C_4H_8N_4O_3$.

Conversion of Formic Acid into Methylaldehyde.—Dr. E. Mulder.—After very briefly referring to his former researches on this subject, the author states that he has obtained a sulphur compound, CH_2S , which, however, was obtained in too small quantity to admit of further experimenting with it.

New Series of Aromatic Hydrocarbons.—Th. Zincke.—The contents of this paper are not suited for useful abstraction.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 7, 1871.

This number does not contain any papers relating to chemistry or collateral sciences.

Journal de Pharmacie et de Chimie, August, 1871.

This number contains the following original papers and essays:—

Researches on the Intimate Action of the Substances which Aid the Decomposition of Chlorate of Potassa while Employed for the Preparation of Oxygen.—Dr. E. Baudrimont.—This memoir is divided into the following chapters:—Action of heat on chlorate of potassa; decomposition of this salt under the influence of substances which do not act chemically upon it; study of the action which certain substances exert upon that compound; discussion of several theoretical matters relating to this subject.

Crystallised Aconitine.—Dr. Duquesnel.—A strictly pharmaceutical paper.

Peculiar and Extraordinary Alteration of the Bread intended for the Army.—Dr. Poggiale.—The contents of this paper bear upon the appearance in some of the bread alluded to of an *oidium*, a cryptogamic vegetable the spontaneous origin of which in the bread is not quite satisfactorily accounted for, but appears to have been more than once, although at long intervals, observed in the extensive

military bakery at Paris. The development of the *oidium (aurantiacum)* alluded to renders the bread unfit for use, and in some degree even poisonous.

Note on the Existence of Copper in certain Waters.—Dr. Roux.—This paper contains the results of some experiments, chiefly made at the request of the Maire of Saint-Jean-d'Angely (Charente Inférieure), bearing upon the question that some of the spring-water of that town had become impregnated with copper, owing to the waste water of a copper-smith's shop having found, by percolation through the soil, its way to the spring. The result of very minutely conducted assays of the soil, as well as of the water in the neighbourhood of the works, revealed the presence of copper, but only in very small quantity. Water from Rochefort, pumped up by the aid of copper pumps, contained rather more copper; but in neither case was the quantity of that metal found in the waters alluded to so large as to be capable of giving rise to any injury to health, the less so as the French, by daily using copper cooking-vessels, obtain from these a sufficient quantity of copper in their system to render the detection of that metal in their blood an easy matter.

La France Scientifique (Ancien Cosmos), October 1, 1871.

This number does not contain any papers relating directly to chemistry or collateral sciences, but we call attention to the title of the first part of an essay:—

The Three Ages of the Globe; Introduction to a Critical Study on Darwinism.—Dr. V. Meunier.

Moniteur Scientifique, Nos. 333 and 354 (double number), September 1 and 15, 1871.

This number opens with a valuable essay:—

Extracts of Meat Considered in a Physiological Point of View.—Dr. P. Müller.—We quote the headings of the different chapters:—On muscular liquid; on beef-tea and meat extracts; on the organic principles present in these substances; action of potassa salts. The following conclusions are drawn by the author from his researches, corroborated by those of a great many others, among these Liebig and Virchow:—Meat extracts are neither directly nor indirectly food, for they do not contain albuminoid matter, neither do the nitrogenous principles which they contain arrest dis-assimilation, that is, they do not prevent the waste of the organic matter which composes the body. In small doses, these extracts are useful by the stimulant action of the potassa salts, which promote digestion and circulation; in strong doses—too large quantity at once—these substances may have a very injurious effect. When given to convalescents from serious diseases, especially if the system is exhausted by prolonged abstinence, the potassa salts present in these extracts in large quantity will act more injuriously because the system has lost a great deal of chloride of sodium; instead of then promoting the nutrition these substances will interfere with it—(1) by the direct action of the potassa salts on the blood globules, whereby the absorption of oxygen of these globules is greatly decreased; (2) by the predominance of such salts in the serum of the blood which only physically dissolve carbonic acid and do not allow the normal quantity of that gas to be exhaled, and thus impede the access of oxygen. Medical men should bear in mind that if given alone these extracts, and the same applies to beef-tea, are no nutriment, and only tend to keep the convalescents weak and not only ill fed but not at all fed.

The following original papers relate to chemistry and collateral subjects:—

The First Idea of a Dial Telegraph.—Dr. Quesneville.—The author quotes a few curious lines taken from a work—"Récréation Mathématique Composé de Plusieurs Problèmes Plaisants et Faciles," edited by Jean Leurechon, c.S.J., Anno 1624, at Pont-à-Mousson—the main gist of which is that the *savant* just named, while speaking of the magnet (loadstone), suggests that if a person, A, had a powerful stone at Paris, and was provided with a dial plate upon which the figures of the alphabet were engraved and to which a movable magnetised needle was adapted, and a person, B, being at Rome, was provided with a similar apparatus, these parties might, by previously agreeing to enter into conversation with each other at a certain hour of the day, so arrange as to be able by the aid of a strong magnet to converse with each other; it appears that there was added to the original text an engraving representing the dial and needles alluded to. The work just spoken of has been re-published in 1626 and in 1629 (printed at Rouen by Ch. Osmont). The passage alluded to also occurs in a work edited in 1636 by Wijnant van Westen, a mathematician at Nymegen (Netherlands) under the title "Mathematische Vermaeckelijkheden;" this work is an improved Dutch translation of the work of Leurechon, who used to write under the pseudonym of H. van Etten.

On Leukaniline.—O. Follenius.—The body just named, $C_{20}H_{21}N_3$, is the product of the reduction of rosaniline, and best obtained in pure state by boiling a solution of fuchsine with pulverised zinc until the liquid has become colourless; from the filtrate, leukaniline in crystalline state separates on cooling; but in order to obtain this substance quite free from rosaniline the residue on the filter should be digested with alcohol, and this solution after filtration, treated with from four or five times its bulk of distilled water, whereby the leukaniline is precipitated. After having been collected on a filter, washed with cold water, and dried, the body is obtained in a pure state. Oxalate and acetate of leukaniline are briefly described; the first named of these salts becomes after a while red-coloured.

Researches on the Artificial Alizarine of Gessert Brothers, Eberfeld (Rhenish-Prussia).—F. Reverdin.—The substance alluded to is met with in commerce in the shape of a thickish yellow-coloured liquid, which was found to contain 10 per cent of colouring matter, consisting partly of alizarine, and partly of a pale orange-coloured crystalline substance, of which too small quantity was obtained to admit of its being analysed, but the author could ascertain that it was not anthraquinone; purpurine was not found in the material. The results of the dye-tests made with the commercial product and the substances obtained therefrom by chemical analysis proved that in every case this artificially-produced material is of first rate quality.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, October 5, 1871.

This number contains the following original papers:—

Comparative Experiments Made with Dynamite and Ordinary Blasting-Powder in Working Quarries and Mines.—F. Hamel.—The first instalment of a paper on this subject. This portion contains a review of the history of discovery, properties, and application of nitro-glycerine and of dynamite.

Description of a Magneto-Electric Machine which Produces a Constant Current.—M. Gramme.—Illustrated by woodcuts. The machine is made and sold by M. Bréquet, 39, Quai de l'Horloge, Paris.

October 12, 1871.

This number contains the following original papers:—

Comparative Experiments Made with Dynamite and Blasting-Powder.—F. Hamel.—Continuation of the treatise on this subject, belonging more to mining and quarrying than to chemistry.

Studies on the Dissociation of Chemical Bodies.—C. Mène.—The continuation of an essay on this subject.

Continuation of the Tabulated Review of the Composition of Fertilising Substances which may be added to Manures, or are fit for use as such by themselves.—C. Mène.

Les Mondes, October 5, 1871.

The greatest part of this number is devoted to an elaborate and valuable paper:—

Geology of the Alps and the Alpine Tunnel.—Professor Sismonda and Dr. Elie de Beaumont.—Illustrated by a lithographic plate.

Quantity of Wood Required for Working a Beet-Root Sugar Manufactory.—M. Simirenko.—The contents of this paper relate especially to Russia.

October 12, 1871.

The only original matter contained in this number relates to some recently-published scientific books of which we quote the following:—

La Chimie Nouvelle ou le Crassier de la Nomenclature Chimique de Lavoisier Déblayé.—C. E. Julien.—This work is written by a well-known engineer, and according to what is stated in the above-named periodical is a production which contains a great deal of valuable matter especially in reference to iron and steel.

Recherches sur les Meilleures Conditions de Construction des Electro-Aimants.—T. du Moncel.

Le Moniteur des Produits Chimiques pour l'Industrie, les Sciences et les Arts et du Matériel de ces Industries Publié par une Société de Chimistes et d'Industriels, October 10, 1871.

In addition to some very elaborate and important papers bearing on political economy, this number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Chemical Products of Italy.—E. Rousset.—This paper, a continuation of former papers on this subject, contains the following sections:—Tallow candles; stearine candles; glue-boiling.

The Lucifer-Match Industry at Marseilles.—P. Bose.—As an instance of the importance of this industry we quote the following:—One firm employs 600 hands, and consumes annually for the production of matches:—25 tons of phosphorus; 7 tons of chlorate of potassa; 15 tons of colouring matter; 8 tons of red lead; 16 tons of refined sulphur; 50 tons of stearine; 25 tons of spun cotton wicks; more than 50 tons of Japan wax; and 100 tons of wood. There is annexed to this factory a chromolithographic printing establishment capable of printing two, three, or six colours, and consuming annually 2000 reams of paper at 500 sheets to the ream.

Engraving on Glass.—A. Ae. Wilbaux.—By the use of types made of an elastic material the author prints on glass fluoride of calcium incorporated in printing ink; the glass thus printed on is next treated at a suitable temperature with sulphuric acid, and after having been washed with water contains in indelible engraving the figures of the types.

Chlorine Preparation.—Tessié du Motay.—The author first prepares chloride of manganese, and heats this in earthenware retorts, admitting at the same time steam and a sufficient quantity of either air or oxygen, but in that case there is also formed hydrochloric acid; if, however, air, or preferably oxygen only, are passed over the red-hot chloride of manganese, chlorine is given off and peroxide of manganese

reproduced. If over this material, heated to redness, a mixture of hydrochloric acid gas and air or oxygen is passed, chlorine is continuously produced and peroxide of manganese regenerated.

Gazzetta Chimica Italiana, 1871.

We have received the first volume (Nos. 1 to 7 inclusive) for this year of this newly-commenced publication, which augurs well for that country which was the land whence science and art spread over Europe, and which now exhibits in every part of its territory a revival of scientific applications and the development of the manifold natural resources. The original papers and memoirs met with in the earlier numbers of this work (a monthly periodical) have been almost simultaneously published in either German or French scientific periodicals, and have been quoted in our columns; but of the original papers, subsequently published, we shall give short abstracts.

Journal für Gasbeleuchtung und Wasserversorgung, Nos. 18, 1871.

The contents of this number bear strictly on matters relating to gas- and water-works' engineering and management.

Bulletin de l'Académie Impériale des Sciences de St. Pétersbourg, Vol. xvi., No. 2, 1871.

This number contains the following original paper relating to chemistry:—

Action of Zinc upon Quadri-Chloro-Benzyl and upon some other Bromated and Chlorated Compounds.—N. Zimine.—The compounds of chlorine and bromine with the hydrocarbons formed by the direct addition of the haloids to the hydrocarbon are violently acted upon by the zinc, the result being the reproduction of the hydrocarbons they are derived from, but the haloid compounds of the hydrocarbons formed by substitution are not thus acted upon by zinc. Quadri-chloro-benzyl, the elementary composition of which corresponds to quadri-chloro-tolan, $C_7H_2Cl_4$, is acted upon by zinc (the compound being placed in hot alcohol), so that half the chlorine is withdrawn and the quadri-chloro-benzyl split up into two compounds, which although of the same elementary composition, $C_{11}H_{10}Cl_2$, exhibit very different physical properties. One of these substances is a crystalline solid body, fusing at 153° , and difficultly soluble in boiling alcohol; the other is nearly soluble in boiling alcohol in every proportion, is also a solid body, has a different crystalline form, and fuses at 65° . Both of these substances are soluble in ether and acetic acid, and not further acted upon by zinc, but by the action of sodium amalgam both these bodies are, when dissolved in alcohol, converted into tolan; at 150° , the two bodies referred to are not acted upon by alcoholic solution of potassa.

No. 3, 1871.

Hydrological Researches.—Dr. C. Schmidt.—This very elaborate and exhaustive essay contains the following sections:—Water of the Glacial Sea, taken at $69^\circ 55' N.$ lat. and $49^\circ 30' E.$ long. from Greenwich; water of the Peipus Lake and of the rivers which feed it. This essay is copiously filled with the results of a large number of analyses of the waters alluded to, and these results are carefully compared with a lengthy series of results of analyses of fresh and salt waters made by other authors.

Eatable Earths from Lapland and Southern Persia.—Dr. C. Schmidt.—Dr. A. Göbel, while travelling in the summer (1870) in Northern Europe ($67^\circ 5' N.$ lat. and $41^\circ 12' E.$ long. from Greenwich), obtained at Ponoï, a village situated on the White Sea, an earthy material which is used by the inhabitants as an addition to flour in bread-baking. A sample of this substance having been forwarded to the author for analysis gave the following per cental results:—Water driven off at 100° , 0.26; water driven off at low red heat, 0.885; alumina, 40.797; peroxide of iron, 0.310; magnesia, 0.618; lime, a trace; soda, 1.829; potassa, 9.845; silica, with a trace of fluorine, 45.506. From this result, as well as from the microscopical examination, the author concludes that this material is not fit for digestion at all. The Persian material was found in the district of Kirman, at 5000 feet above sea-level ($30^\circ 10' N.$ lat. and $58^\circ 10' E.$ long. from Greenwich). The substance locally known as "G'hel i Giveh" is met with in the shape of lumps of the size of an apple, is converted by the action of water into a soft slimy mass, and is very readily soluble in dilute acids, even in dilute acetic acid. The percentage composition of this substance was found to be:—Carbonate of magnesia, 66.963; carbonate of lime, 23.634; chloride of sodium, 3.542; sulphate of soda, 0.293; carbonate of soda, 0.598; hydrate of magnesia, 1.311; peroxide of iron, 0.092; alumina, 0.227; silica, 0.765; water of combination driven off at 120° , 1.153; hygroscopical water, 1.422. Since the inhabitants of the country here alluded to bake bread from flour which is fermented as so to become sour, the addition thereto of some of the powder of the mineral here alluded to will have the effect of a kind of baking-powder, and at the same time neutralise the acid.

On some of the Properties of Trimethyl-Carbinol.—Dr. A. Boulterow.—Notwithstanding the high scientific value of this exhaustive memoir, its contents are not well suited for any useful abstraction; an observation equally applying to the following papers, which would also require the reproduction of very lengthy and complex formulæ:—

On Triethyl-Carbinol.—Dr. A. Nahapetian.

Dimethyl-Pseudo-Propyl-Carbinol.—J. Prianchikow.

On a New Body Isomeric with Amylen.—M. Ermolaiw.

No. 4, 1871.

The original papers and memoirs contained in this number do not relate to chemistry or collateral sciences.

NOTES AND QUERIES.

A Curiosity in Water Analysis.—The following amusing analysis of the "Chalybeate Springs" appears in page 10 of the "Concise Guide to Tunbridge Wells and Surrounding Neighbourhood," recently published, and sold everywhere in the town:—"The water is clear, bright, and colourless; the taste savours strongly of steel, but is not disagreeable, and it has scarcely any smell, though sometimes in a dense air its ferroginous exhalations are very distinguishable. When first taken up in a large glass, its particles continue at rest till it is warmed to nearly the heat of the atmosphere, when some airy globules begin to separate and adhere to the glass, and in a few hours a light copper-coloured scum begins to float on the surface, whilst an ochreous sediment settles at the bottom. From the experiments of different physicians, it appears that the component parts of this water are steele particles, marine salts, an oily matter, an ochreous substance, a volatile spirit too subtle for analysis, and a simple fluid." Perhaps some one of your readers could manufacture an artificial mineral water from the above analysis for the benefit of those unable to visit the springs!—J. J. M.

MEETINGS FOR THE WEEK.

MONDAY, Oct. 30th.—London Institution, 4. Prof. Huxley, LL.D., F.R.S., on "Elementary Physiology (I)."
THURSDAY, Nov. 2nd.—London Institution, 7.30. Dr. J. H. Gladstone, F.R.S., on "Michael Faraday: the Story of his Life."
Chemical, 8. W. H. Perkin, F.R.S., on "Anthrax-flavie Acid."

TO CORRESPONDENTS.

* * Vol. XXIII. of THE CHEMICAL NEWS, containing a copious index, is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxiv. commenced on July 7th, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each, post free, may also be obtained at the Office.

7. C.—Single numbers of the foreign journals cannot often be purchased, so that no object would be gained by our adopting the course you propose. A foreign bookseller will give you the subscription prices.

7. Instone.—You will find full particulars about testing carbolic acid in "On the Application of Disinfectants in Arresting the Spread of the Cattle Plague," by William Crookes, F.R.S. The price is 1s.; it can be had on application to our publisher.

BOOKS RECEIVED.

An Introduction to Practical Chemistry, including Analysis. By John E. Bowman, F.C.S., late Professor of Practical Chemistry in King's College, London. Edited by Charles L. Bloxam, F.C.S., Professor of Chemistry in King's College, London.
Report on Spiritualism of the Committee of the London Dialectical Society. London: Longmans and Co.
A Systematic Handbook of Volumetric Analysis. By Francis Sutton, F.C.S. Second edition. London: J. and A. Churchill.
On the Relative Powers of Various Substances in Preventing the Generation of Animalculæ, or the Development of their Germs, with Special Reference to the Germ Theory of Putrefaction. By John Doogall, M.D. London: J. and A. Churchill, New Burlington Street.
Sixth Report of the Quekett Microscopical Club, and List of Members.
New Remedies. A Quarterly Retrospect of Therapeutics, Pharmacy, and Allied Subjects. Edited by Horatia C. Wood, jun., M.D. New York: William Wood and Co.
Lecture on the Analysis of Coal-Gas. By Henry Lethaby, M.B., M.A., &c. Delivered before the British Association of Gas Managers. London: William B. King.
The Use of Gas in the Laboratory.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

THE CHEMICAL NEWS.

VOL. XXIV. No. 623.

ON CERTAIN REACTIONS OF THE SULPHO-CONJUGATED ACIDS OF PHENOL.

By C. GIRARD and G. DE LAIRE.

MORE than a year ago, Messrs. Dusart and Bardy patented a process for the preparation of certain secondary monamines of the aromatic series. The process, which, according to its authors, was a general one, consisted in submitting a primary aromatic monamine to the action of the sulpho-conjugated acids of phenol. They quoted in particular the production of diphenylamine by the action of phenol-sulphuric acid or a phenol-sulphate upon aniline at a temperature of 200° to 230° C. According to these chemists the phenol loses its hydroxyle, the phenylic residue replacing one of the atoms of ammoniacal hydrogen of the aniline.

This reaction is in contradiction to what is known of the constitution of phenol and its sulpho-conjugated derivatives, and, moreover, we endeavoured some years ago, and always without success, to replace the available hydrogen in aniline by the phenyl radical contained in phenol.

The unexpected result announced by Messrs. Dusart and Bardy has induced us to undertake further experiments on this subject.

(1). We heated for two days in a closed tube at 250° to 280° one molecule of phenol-sulphate of sodium and one molecule of aniline. The tube contained at the end of the experiment a liquid and a solid portion. On opening it there was no evolution of ammonia; we observed only the characteristic odour of sulphurous acid. The liquid portion contained aniline and unaltered phenol; the solid portion was composed of sulphate, sulphite, and sulphide of sodium. We could discover no diphenylamine whatever, and with the exception of an insignificant loss of 2 or 3 per cent, the whole of the phenol corresponding to the phenol-sulphate was recovered.

(2). We repeated the previous experiment under the same conditions of time and temperature, but employing an excess of aniline, 2 or 3 molecules of aniline for 1 molecule of phenol-sulphate. On opening the tube there was a considerable evolution of ammonia and a strong smell of sulphide of ammonium. The contents of the tube were partially liquid and partly solid. The former was composed of aniline, phenol, and diphenylamine. The solid portion contained sulphate, sulphide, hyposulphite, and sulphide of sodium. These experiments, several times repeated, show clearly that the formation of diphenylamine is not due to the substitution of the phenylic residue in phenol for the ammoniacal hydrogen of the aniline, but simply to the action of aniline upon one of its salts. This was to be expected on theoretical grounds, and has been thoroughly confirmed by experiment.

ON THE ESTIMATION OF ANTIMONY, AND THE

SEPARATION OF ANTIMONY FROM TIN, FROM ARSENIC,
FROM TIN AND ARSENIC, AND FROM THE OTHER
METALS, BY MEANS OF A NEW PRECIPITATING
REAGENT OF ANTIMONY.

By HUGO TAMM.

WITH the exception of sulphuretted hydrogen, there is no real precipitating reagent of antimony known to chemists;

* French Patents; Girard and De Laire, March 21, 1866. *Moniteur Scientifique*, April 1, 1867; Feb. 1, 1868; Sept. 15, 1869.

for although the number of reagents, both organic and inorganic, which precipitate this metal is very great, in every instance known the precipitation is incomplete, and a very large proportion of the metal remains in solution, so that all those reagents are unfit for the estimation of antimony.

It is a great pity, for some of them, such as water or oxalic acid, would be admirably adapted for this purpose. But analysts must submit to the whims of nature, over which they have no command whatever, and it is only by patient labour, untiring perseverance, and, above all, luck, that they can overcome practical difficulties.

One method being always insufficient for the estimation and the separation of a substance in all cases, if I propose a new process for the estimation of antimony it is not in view of substituting it to the method which has rendered such great services to analysis, but, on the contrary, to strengthen it by means of a powerful auxiliary, for accurate estimations and neat separations leading to trustworthy results and to complete analysis can only be obtained by the judicious use of several methods.

The process which I am going to describe will be found most useful in most cases, and sometimes absolutely indispensable.

It was neither chance nor analogy which led me to discover it, but I was sensible to the defects of the old methods, and thoroughly disgusted with the clumsy and generally difficult processes hitherto proposed for the separation of antimony from tin and arsenic, and I resolved to find out some simple means of estimating antimony, and of separating it from tin and from arsenic.

After a careful investigation of the precipitating properties of all the substances of which I could lay hold of, and which were likely to effect the object I had in view, luck pointed out to me the following method:—

Estimation of Antimony in the State of Bigallate of Teroxide of Antimony.

When a neutral and concentrated solution of terchloride of antimony is mixed with a slight excess of gallic acid, all the antimony is precipitated in the state of a double gallate of teroxide of antimony and water, or, to use the ordinary notation, as bigallate of antimony, or antimonic bigallate.

A neutral or slightly acidulated solution of terchloride of antimony, corresponding, in fact, to strongly acidulated solutions of ordinary metals, the precipitation of antimony takes place in a regularly acidulated liquor, since besides the free hydrochloric acid present, all the combined hydrochloric acid is liberated by gallic acid.

In this acidulated liquor, bigallate of antimony is almost completely insoluble, and in the liquor separated by filtration from the precipitate, sulphuretted hydrogen reveals but a minute quantity of antimony which can be neglected for most practical purposes.

In those conditions, antimony is the only metal precipitated by gallic acid. All the other gallates, even those which are insoluble in water, are extremely soluble in the liquor from which antimony has been precipitated, and, consequently, gallic acid affords an easy means of separating at once antimony from the other metals.

It follows, also, that gallic acid is a very perfect precipitating reagent of antimony; in fact, it has only one defect, it is a non-volatile organic acid, and as such, it alters the behaviour of some metals with some of their precipitating reagents, so that after the separation of antimony, it is sometimes necessary to precipitate by sulphuretted hydrogen or by sulphide of ammonium the metals left in the solution. But as this operation would, in many cases, have to be performed for convenience sake, it matters but very little. On the other hand, most metals can be precipitated, even in presence of an excess of gallic acid, by means of appropriate reagents, and I shall carefully indicate when and how this can be done, and when, on the contrary, the metals must be precipitated as sulphurets.

Precipitation of Bigallate of Antimony; Washing, Drying, Weighing, Behaviour, and Composition of this Precipitate.—On a New Phenomenon called Hygraffinity.

As I have stated above, the solution of terchloride of antimony must be neutral or only slightly acidulated, and what is most important, the solution must be concentrated. The reason of this is obvious, for bigallate of antimony is partially or in totality soluble in hydrochloric acid, according to the quantity of this acid present in the liquor, and as it is well known, the weaker a solution of antimony is, and the more acid is required to keep it clear, while the more concentrated the solution of antimony is, and the more neutral it can be obtained.

After that a strong and neutral solution of terchloride of antimony has been prepared, only a slight excess of gallic acid should be added. To ascertain this, the following test is employed:—

After the addition of a quantity of gallic acid apparently sufficient to precipitate all the antimony, the precipitate is allowed to subside. A glass rod is dipped in the supernatant liquor, and a drop of this liquor is placed on a piece of white paper. To this a drop of ammonia is added, and the slightest excess of gallic acid present is indicated by the nice pink colour which appears.

If too much gallic acid had been used, this excess of acid would in no way impair the accuracy of the estimation of antimony, and if it is recommended not to use more of this acid than is required for the complete separation of antimony, it is chiefly to simplify the separations and estimations of the metals left in solution.

The solution of gallic acid used for the precipitation of antimony must be quite recently prepared; for in a solution of some days standing, gallic acid is altered by a peculiar phenomenon of hydration, whereby it becomes unfit for the complete precipitation of antimony. That this alteration in the composition and the properties of gallic acid is only due to hydration is proved by the fact that the solution evaporated to dryness leaves a residue of gallic acid, which, when re-dissolved in water, is perfectly fit for the complete precipitation of antimony. This phenomenon of hydration is analogous to the phenomena exhibited by phosphoric acid.

Bigallate of antimony is a very white precipitate, somewhat bulky, but which settles very rapidly. It cannot, however, be washed on the filter, not even on a double filter, for it invariably passes through the filter as soon as the acidulated mother-liquor has been washed away. But as it settles very rapidly in liquors, the mixed mode of decanting and filtering must be resorted to, and in this instance this process presents no inconvenience and no difficulty. The only disadvantage is that more washings are obtained than would be the case with simple filtration. For this purpose, the precipitate is allowed to settle, the liquor is poured on the double filter and decanted as closely as possible from off the precipitate. This done, the flask holding the precipitate is re-filled with hot water, the precipitate is allowed to settle once more, and once more the supernatant liquor is filtered and decanted as closely as possible from the precipitate. The same operation is repeated three or four times; the precipitate is then placed on the filter, where it can be washed once or twice with safety.

The tedious description of this tedious operation has its importance, as, by following to the letter the indications here given, much trouble and inconvenience will be avoided.

The drying of gallate of antimony, with the usual precautions, is very easily effected in the water bath at the temperature of 100°C ., and the formula of the precipitate thus thoroughly dried is then $\text{SbO}_3(\text{C}_7\text{H}_3\text{O}_3)_{23}\text{HO}$, and it contains exactly 40.85 per cent of metallic antimony.

In the estimation of antimony, the dried bigallate should be weighed as soon as it has cooled, or, better still, shortly after it has been left to cool in a dried atmosphere, for it has a great affinity for water, which it absorbs rapidly from the air.

When bigallate of antimony, dried at 100° , is left exposed to the air for a few hours, it is found to absorb exactly two equivalents of water, and its formula is then identical with that of bigallate of antimony dried at the temperature of 80°C ., and which is represented by—

This new bigallate of antimony is the normal compound; it contains exactly 38.77 per cent of metallic antimony, and it could be used as well as the other one for the estimation of antimony, but there is evidently no advantage in so doing.

When the bigallate of antimony dried at 80°C . is placed in the water-bath and dried at 100°C ., it loses two equivalents of water, but on being left exposed to the air for some time it re-absorbs those two equivalents of water, which it loses by another desiccation at 100°C ., and which it re-absorbs once more by a fresh exposure to the atmosphere.

This curious experiment can be repeated indefinitely with the same success, and this fact is so very remarkable that although I have the strongest objection to the introduction of new words in science, I have no alternative but to give a name to this extraordinary phenomenon, and I shall call it, for convenience sake, *Hygraffinity*, or *Chemical Hygrometry*, to distinguish it from physical hygrometry, as it is observed in artificial silica, oxide of copper, and a number of insoluble substances.

I believe that bigallate of antimony affords the first example of an insoluble precipitate exhibiting such a powerful affinity for water. I cannot believe that this example is unique, and I trust that it will be the basis of an interesting investigation of similar phenomena not yet observed in insoluble compounds, and I have no doubt that it will be among the organic insoluble compounds of metals that the most interesting facts connected with this phenomenon will be discovered.

The estimation of antimony in the state of bigallate dried either at 80°C . or at 100°C . is very accurate indeed when the precautions indicated have been observed. But it is not absolutely necessary to estimate this metal in this state, even after it has been separated as bigallate, for, as I have stated before, bigallate of antimony is extremely soluble in weak hydrochloric acid, so that, after it has been placed on the filter, it is only necessary to dissolve it in hydrochloric acid, to wash well the filter with dilute hydrochloric acid, and to precipitate the solution thus obtained by sulphuretted hydrogen, to be enabled to estimate antimony as usual in the state of tersulphide. The sulphide of antimony obtained in these conditions is chemically pure, and all that is required to apply it to the estimation of antimony is to wash it well until the washings mixed with a little ammonia exhibit no pink colour indicative of the presence of gallic acid.

On the whole, it is, perhaps, best to follow, as a rule, this last process, but it must be resorted to when the analyst has not got at his disposal the proper appliances for drying and for cooling the bigallate of antimony.

Remarks.—When antimony has been estimated as bigallate, or separated in this state from metals insoluble in sulphide of ammonium, an excellent precaution to take to ascertain the perfection of the separation is to dissolve the bigallate of antimony which has been used for the estimation of antimony in an excess of sulphide of ammonium.

There ought to be no residue of black sulphides insoluble in this reagent.

Preparation of the Solutions of Terchloride of Antimony required for the Separation and Estimation of Antimony in the state of Bigallate.

Were it not for the remarkable reaction which I am going to describe, gallic acid could be used only in very limited instances,—in those only in which the antimonial

compound dissolved in hydrochloric acid gives at once a solution of terchloride of antimony, for solutions of perchloride of antimony are quite unfit for the estimation of this metal by gallic acid, and most reducing reagents act very indifferently on perchloride of antimony, or do not act at all, or are the means of introducing in the solution substances difficult of separation, and which, as a rule, disturb known reactions, and prevent, in most cases, neat separations and accurate estimations. But when a solution of perchloride of antimony, slightly acidulated with hydrochloric acid is mixed with iodide of potassium, two equivalents of chlorine combine with two equivalents of potassium; two equivalents of iodine are liberated and the perchloride of antimony is reduced to the state of terchloride, $\text{SbCl}_5 + 2\text{KI} = \text{SbCl}_3 + 2\text{KCl} + 2\text{I}$.

This important reaction will prove most useful, as by its means perchloride of antimony can, at will, be converted into terchloride with the utmost facility, by the introduction of two substances, one of which, iodine, is evolved, the other, potassium, remaining in the liquor, and aiding, as I will show, to the accuracy of the estimation. Consequently, whenever there is the slightest doubt about the composition of a solution of antimony obtained by some means or other, it is only required to heat the solution with a slight excess of hydrochloric acid and a little powdered iodide of potassium. When no iodine is evolved, it is because the whole of the antimony exists in the state of terchloride; when, on the contrary, iodine is evolved, it is because part or the whole of the antimony exists in the state of perchloride, and it is only necessary to add iodide of potassium little by little until no more free iodine is evolved to be certain that the whole of the antimony is reduced to the state of terchloride.

In general it is useless, and it may sometimes be inconvenient, to add more iodide of potassium than is required for the complete reduction of perchloride of antimony, but with a little experience nothing is easier than to judge when the proper quantity of iodide of potassium has been added. This is invariably the case when the clear liquor freed from iodine and mixed with a little more iodide of potassium remains clear, is not deeply coloured, or evolves no more free iodine.

The solutions of terchloride of antimony thus prepared and properly concentrated by slow evaporation are then quite ready to be precipitated by gallic acid.

Estimation of Antimony in Native Sulphuret of Antimony.

The estimation of antimony in this important mineral is very easily effected by means of gallic acid, and its complete and accurate analysis, which was very difficult and almost impossible by the old methods, has become quite simple by the gallic acid process.

Twenty grs. of the powdered mineral are treated by a slight excess of hydrochloric acid, and the mixture is gently heated until the whole of the sulphuretted hydrogen disengaged is thoroughly evolved. The solution is then filtered, the filter and matrix are washed with dilute hydrochloric acid, and the solution is slowly evaporated in the flask until it is conveniently concentrated and freed from the excess of hydrochloric acid.

In this solution the whole of the antimony exists in the state of terchloride, a slight excess of a recently prepared solution of gallic acid is added, with the precautions already indicated. Hot water is then added, and the precipitate of bigallate of antimony is washed, dried, and weighed, as has already been stated. Antimony may also be estimated as sulphide after having been separated as bigallate.

Twenty grs. of this mineral are quite sufficient for the estimation of antimony, but in the complete analysis it would be inconvenient to operate upon more than 50 grs. as the precipitated bigallate of antimony is very bulky.

Antimony being separated as above, iron, lead, copper,

silver, arsenic, and sometimes zinc, cobalt, and other metals remain in solution.

Arsenic exists much less frequently than is generally supposed, and I really do not know to what to attribute the universal belief that arsenic follows antimony everywhere, except to the imperfect or difficult methods hitherto employed for their separation, leaving a wide scope to the imagination of analysts.

Copper, on the contrary, is very often present. It can be estimated here with the greatest accuracy, as the whole of it exists, or may be made to exist, in the filtrate. By the old methods, on the contrary, it was constantly hidden by antimony which it followed in the successive operations of the analysis, since it was precipitated along with antimony, and nearly all taken up by the sulpho-antimoniate of ammonia formed by treating sulphide of antimony by sulphide of ammonium.

Although it was then possible to detect copper by attacking sulphuret of antimony by nitric acid, a large portion of copper was maintained in an insoluble state by the antimonious acid formed, so that it was not possible to estimate it with anything like accuracy.

The analysis of the filtrate is proceeded with as that of an ordinary liquor containing the metals mentioned. The only metal which cannot be properly estimated in this liquor is iron, the presence of gallic acid preventing its precipitation, even by means of sulphide of ammonium, but its complete separation from antimony is so simple by the known methods that I need only mention this fact, remarking, at the same time, that in this, as in most instances, one method is insufficient, and that correct analyses can only be made by the judicious use of several appropriate methods.

Estimation of Antimony in the Artificial Sulphide of Antimony in the Course of Analyses.

In the course of a complicated analysis, it is oftentimes absolutely necessary to obtain antimony first in the state of a sulphide of antimony mixed with a large quantity of sulphur, and contaminated with small, or, as the case may be, large, proportions of sulphides of copper, arsenic, or tin.

The gallic acid process affords a simple means of carrying out a careful analysis in this part of the operation, and of estimating antimony by a direct process.

For this purpose the collected mixture of sulphur, sulphide of antimony, &c., &c., wet or dried, is first of all treated by hydrochloric acid, and when the action has ceased a little chlorate of potash is added, to attack any copper or arsenic which might have escaped the action of the acid. The solution thus obtained decanted from off the residue of sulphur is evaporated, reduced by iodide of potassium, and precipitated by gallic acid. In all this the mode of proceeding is identical with the process fully explained in the next example.

(To be continued)

REPORT ON THE MOLECULAR DISSOCIATION BY HEAT OF COMPOUNDS IN SOLUTION.

By CHARLES R. C. TICHBORNE, F.C.S., M.R.I.A., &c.

(Continued from p. 203).

Experiment II.

THE addition of alkaline salts to the ferric compounds determines more easily the precipitation or dissociation. Therefore, the iron alums, either with the ammonia or potash base, exhibit this phenomenon in a marked degree. These alums, which show a beautiful but very faint amethyst tint, gave on solution in the cold a slightly coloured liquid, made paler on the addition of a very dilute solution of sulphuric acid. The gradual increase of temperature brought about all the reactions and phenomena

observed in the above experiments, only in a much more marked and decided manner, whilst, again, this lowering of the thermanalytic point was even more evident with the potash alum.

It is unnecessary to detail the experiments performed with the solutions of ferric chloride, because the results were almost the same. I would wish, however, to observe, that even on prolonged boiling there seems to be no loss of HCl at ordinary atmospheric pressure.

It having been determined that the first results of the continuous boiling of a neutral ferric salt is the precipitation of a basic salt, containing a part of the stylos element, further experiments were performed to determine how far these acid molecules were removable at ordinary atmospheric pressure, by the combined and continuous action of water and heat.

Experiment 12.

A large quantity of a dilute solution of ferric sulphate was submitted to continuous boiling until a considerable precipitate was obtained. This precipitate was collected upon a filter, washed once and dried at 100° C. 0.219 grm. gave 0.141 of ferric oxide when dissolved in HCl, precipitated with ammonia, and weighed after ignition. This corresponds to 64.4 per cent of ferric oxide. A portion of this precipitate before drying was placed in a considerable body of water, and again submitted to a temperature of 100° C. for two hours. After this treatment the appearance was much changed; the colour which was originally of a light ochrey yellow, had been changed to a reddish-brown, whilst the precipitate became much denser. 0.388 grm. now gave 0.32 grm. on precipitation, as in the previous estimation, and therefore corresponds to 82.5 per cent; it, however, still contained a trace of the basic salt. The further action of heat upon these basic salts will be found described in Experiment 16.

It must be borne in mind that all the above experiments had been performed with what we might call chemically neutral salts, but it is probable that from a geological point of view there would be formed Fe_2O_3 , or a deficiency of one-third of the acid, e.g., from the oxidation, for instance, of iron pyrites. In such a case we would have to start with a basic solution, the first result of the oxidation of the pyrites being a ferrous salt, which ultimately becomes oxidised into the ferric.

Experiment 13.

To a weighed quantity of pure crystallised ferrous sulphate a quantity of pure nitric acid was added, sufficient to exactly oxidise the ferrous salts to its higher term. The acid was allowed to remain in contact with the powdered salt without the addition of water, until on dissolving a portion, and after warming and testing with ferricyanide of potassium, all trace of the magnetic salt had nearly disappeared. This product was then diluted with 50 times its weight of water: such a solution is perfectly clear, and will remain so for some little time, but ultimately it decomposes spontaneously at ordinary temperatures, the time being determined by the amount of dilution and temperature. When diluted so as to represent 0.5 per cent, a given volume (a) of this liquid gave on precipitation with ammonia and on ignition 1.557 grms. of ferric oxide. In a second determination, the solution was brought to 100° C., and maintained at that temperature for some time; the precipitate that fell was separated from the liquid by filtration, washed with a small quantity of water, and dissolved in hydrochloric acid, and the oxide estimated in this solution with ammonia, as in the first instance. 0.559 grm. was procured, which is over the amount of base really in excess of the acid present, $\frac{a}{3} = 0.519$ grm. The filtrate again on dilution and boiling gave a precipitate representing 0.049 grm. of oxide. The filtrate again on dilution and boiling became opaque, but it was not necessary to follow out this experiment further, it being

evident that there was no actual limit. It is probable that many of the ores, such as hæmatite, brown iron ore, bog iron ore, ochres, &c., are formed in somewhat a similar manner to that detailed, and it is curious to observe that sulphuric acid is seldom absent from such hydrated minerals and frequently in much larger quantities than the published analyses would lead one to suppose (*vide Analyses*).

We have now to consider the action of heat upon such fluids under pressure.

Experiment 14.

A solution of ferric sulphate was placed in a tube of hard German glass* and hermetically sealed. This tube was then placed in a gun-metal apparatus, capable of bearing a considerable pressure, a little water being placed in the apparatus to equalise the pressure outside the glass tube, the heat was gradually raised until a thermometer, the bulb of which was placed in a cavity outside the apparatus, marked 177° C. The whole apparatus was maintained at this temperature for two hours. On cooling and taking out the tube, it was seen that a similar decomposition had taken place as that obtained under ordinary atmospheric pressure, only in a more marked manner. At the bottom of the tube there was a considerable precipitate of an ochry nature, consisting of basic sulphate; but at the surface of the fluid there was an incrustation composed of red oxide of iron, adhering to the side of the tube in the form of a ring.

Experiment 15.

This was a modification of the previous one, but in this case a more volatile stylos element was chosen, and although it was placed in a tube, as in the previous experiment, the orifice was left unsealed. We were, therefore, on placing it in the apparatus described above, submitting the fluid to the action of a considerable volume of steam, at a pressure of nine atmospheres. After two and a half hours' digestion the contents of the tube presented a remarkable appearance. The greater part of iron lay at the bottom of the tube, not in the form of a basic precipitate, but as a dark and heavy oxide of iron. Thin layers of this oxide adhered to the tube at the surface of the fluid, which, when examined by the microscope were seen to be transparent and brilliantly red; by reflected light they possessed a blackish metallic lustre. The tube still contained an acid salt of iron, which, however, no longer acted upon the enclosed oxide; the latter seemed anhydrous.

In the first experiment (Expt. 14) there can be no doubt that a similar change had partially taken place, but only to a slight extent; it was the limited volume of steam generated in the tube reacting upon the surface of the fluid that formed the ring of ferric oxide. Certain specimens of specular ore (Analysis 4) are formed in this manner. They are simply pseudomorphs of the sublimed and anhydrous ferric chloride, produced by volcanic agency, and ultimately submitted to the action of high pressure steam.†

Experiment 16.

The basic precipitate procured upon boiling a solution of ferric sulphate at ordinary temperatures, was next placed in a tube with a little water, and submitted to the action of steam for two and a half hours, at a temperature of 177° C. The result was the gradual conversion of the basic precipitate, which lay at the bottom of the tube to the extent of about 15 millimetres, into a bright red and dense precipitate, which, however, gradually assimilated its original appearance until, at the depth of 6 millimetres, it appeared to have retained its primitive

* It is necessary in these experiments to have a good glass, as some specimens of lead glass seem to be rapidly acted upon at high temperature by some of the solutions used.

† In speaking upon this subject in his Lectures on Chemical Geology, Dr. Percy says, "Supposing we have the vapour of sesquioxide of iron, there is no difficulty in accounting for the formation of this sesquioxide in volcanic regions. If that vapour be brought in contact with the vapour of water, we get a deposit of crystallised sesquioxide of iron, with the formation of hydrochloric acid."

composition and ochry appearance. Some considerable proportion of this precipitate seemed to have been carried up the side of the tube. At the line of juncture of steam and fluid, this precipitate was converted into anhydrous oxide of iron; above this the basic salt was intact, except that it seemed to be perfectly dehydrated and white, and it was not until it had been in contact with the fluid contained in the tube that it seemed to regain its original appearance. It is evident, therefore, that as regards the more fixed and non-volatile acids no dissociation is effected at the temperature tried, except in the presence of condensed water, but that the steam is capable of removing water of hydration under such conditions.

Before disposing of these experiments I should wish to draw attention to some speculations upon this subject which have been promulgated by Dr. Percy in his lectures on Chemical Geology. "It" (ferric oxide) "is found pseudomorphous after iron pyrites. It is a puzzle to know exactly how this pseudomorphism has taken place. "If iron pyrites is exposed to the weathering action of the air, it is converted, and must be converted first of all into a common sulphate of protoxide of iron, that becomes oxidised by exposure to the air, passing to the state of a sulphate of sesquioxide of iron. That sulphate of sesquioxide of iron, by the action of water, decomposes into two salts—an acid salt which will dissolve away, and a more basic salt which would remain. We can easily understand the transformation of iron pyrites, under these conditions, into a highly basic sulphate, and even into hydrated sesquioxide, because we have only to call into our aid bicarbonate of lime, which frequently occurs in mineral waters. The trace of sulphuric acid might be easily removed, and the gypsum formed washed away, leaving nothing but hydrated sesquioxide of iron in the manner described, and then exposed to a certain degree of heat whereby the water of the hydrate may be expelled, and the red oxide left. But that theory will not suffice, because we find certain crystals of hydrated sesquioxide of iron which are partially converted on the outside into red oxide of iron. It is perfectly evident that the temperature sufficient to decompose the hydrate could never have existed when such crystals were formed, because if it had, it is impossible to conceive that any nucleus of hydrated sesquioxide of iron should remain. The formation of this anhydrous sesquioxide of iron in nature is yet unexplained satisfactorily. We can produce it readily enough in our laboratories by means of heat, but there is no reason for supposing that in the condition in which it has been produced in nature, a high temperature has prevailed, or, at least, that remark applies to many cases of the formation of that mineral."

As regards the ultimate removal of the sulphuric acid, it would seem from the experiments detailed, that it is not absolutely necessary to call in the aid of a second base, such as lime, it being quite possible and probable that the same results may be obtained, under the laws of dissociation, by the aid of immense pressure and a long period of time, such as would be procured in geological changes.

Again, as we see that we can have perfect dehydration even in the presence of water or steam, the second difficulty which presents itself in the crystals of anhydrous oxide containing the nucleus of hydrate is disposed of.

The chromic oxide behaves exactly in a similar manner, except that, *ceteris paribus*, the point of dissociation is higher, and therefore it requires more careful investigation to observe the changes produced by heat upon its compounds in solution, which so far have escaped observation or have been misconstrued.

It is well known that the ordinary chromic salts present a "peach blossom" colour when in solution, convertible by heat into green solutions. The most rational of the many explanations given of this phenomena is one of dehydration, but there is something more than this. Theoretically, it would seem that the chromatic change was due to basicity of the solution as

in the ferric salts, and that it was only necessary to increase the boiling-point of the solution by pressure, or to increase the condition of basicity by the volume of water to obtain similar results to those obtained with iron. This was satisfactorily verified with many experiments, a few of which will suffice to illustrate this part of my subject.

Experiments 17 and 18.

Solutions of chromic sulphate and potassio-chromic alum, when submitted in tubes for the space of two to three hours in the pressure apparatus, gave, in each case, basic precipitates, the temperature being 177° C. The precipitate in the last-named substance being very voluminous, I did not succeed in procuring anhydrous chromic oxide corresponding to the ferric oxide, but look upon its consummation as merely a matter of pressure.

Experiment 19.

A dilute solution of any chrome alum, if dropped into a flask of boiling water, is instantly dissociated. The contents of the flask become quite opaque, and the basic precipitate is palpable to the eye. This precipitate is re-dissolved on cooling, and even during boiling if the solution of chromic alum is gradually added.

If we accept the theory, of which there can be little doubt, that there can co-exist a base and an acid salt in solution, this explains at once the change of violet salts of chromic oxide into green solutions on boiling. Any neutral salt of chromic oxide dissolved in the cold gives a violet colour contaminated with green ("peach blossom"?). This, as in the iron salt, is due to the basylous action of the water. The cautious addition of dilute sulphuric acid converts it into nearly a pure violet. It is converted into the green solution either by the addition of an alkali, by the addition of water, or by heat. In other words, the green colour in chromic salts is due to the basylous condition. In the case of heat, the green solution regains, after some time, its original condition, but only slowly. Many explanations have been given of this phenomenon, and it seems almost strange that one so simple should have escaped observation.

The aluminic oxide also obeys the same law of dissociation, only in a still less marked manner. It was evident that from analogy this should be so, although at the first glance it would appear that such was not the case. But, on taking into consideration the relative atomic position of the elements concerned, it would be seen that dissociation could be only exerted at ordinary pressures to a very limited extent as regards this base; thus there is no evidence of decompositions in solutions of any considerable strength on boiling, but if a very considerable proportion of water is there to the amount of salt, a basic compound thereof is precipitated at 100° C. This is best seen by passing a beam of electric light through the flask, as the precipitate formed is almost optically invisible in daylight. A beam of electric light impinging upon the light flocculent precipitate at once reveals its existence. It is almost absolutely necessary to use some such light when operating upon chloride of alumina, but an aluminic alum, by virtue of the extra play of affinities brought to bear, gives a reaction easy of observation by the eye: these precipitates re-dissolve on cooling. As regards the effects of extraordinary heat procurable under pressure, we find that alumina behaves in a similar manner to the other members of this group, which the following experiments will illustrate.

Experiment 20.

The ammonia and potash alums were placed in separate sealed tubes, and submitted for 2½ hours to a temperature of 177° C. White crystalline precipitates were produced, varying in composition, but containing sulphuric acid. They represented the greater part of the alumina present

Experiment 21.

An open tube containing a solution of chloride of aluminium was placed in the same apparatus (described in

the iron experiments) and submitted for some hours to a temperature of 177° C. At the line of juncture of fluid and steam a white colloidal substance was deposited, which seems to consist of a mixture of hydrated and anhydrous alumina. This experiment may throw some light upon the formation of corundum. Sapphire, ruby, and topaz have been formed artificially with perfect success by Ebelmen, Deville, and others; all these artificial processes, however, have been igneous ones. In nature, however, it is evident that the corundum is not always, if it is ever, formed in this manner. It frequently contains from 3 to 4 per cent of water, and is also associated with diaspore and other hydrated minerals.

Before concluding this part of my report, I will consider for a moment the results of these experiments collectively. It would seem that the compound molecules of aluminic, chromic, and ferric oxides are dissociatable in ratio to their atomic weight; or, we may say, as regards this group, that their basylous position is in ratio to their dissociability. Thus, although compound alumina molecules are dissociatable at ordinary temperatures when insufficiently dilute the decomposition is not so well marked until we get an extraordinary pressure, and the corresponding increase in the range of temperature. Again, that in the presence of other compounds of basylous elements they are more easily dissociated from the introduction of a second basylous molecule reacting upon the acid. The following series of experiments upon the alums and simple salts will place what is stated in a clearer light. Some of them were performed by taking very diluted but standard solutions of the typical salts and adding, degree by degree, to them, whilst in a state of ebullition, water until the thermanalytic point was reached; they were so arranged that the evaporating water was re-condensed and flowed back into the flasks. The water was distilled twice, the first time from a small quantity of acid sulphate of potassium to render it free from all trace of ammonia. The flasks were made of hard German glass, and were digested with dilute hydrochromic acid for some time before they were used. It was found impossible to obtain water by filtration through paper that would stand the test of a beam of the electric or lime-light. The clearest water was obtained by subsidence after distillation from a silver retort. Except in a few cases, most of the experiments can be followed by performing them by gas-light. The flasks must, in this case, be carefully cleaned, and a powerful gas-flame be placed opposite the manipulator and behind the flask. The faintest precipitate will be perceived by this means on holding the flask close to the eye, providing it is not of that peculiar transparent and colloid nature sometimes observed in modifications of alumina and silica.

The solutions used were weak, but were so proportioned that each contained an equivalent quantity of the trioxide to correspond to 1 grm. of chloride of aluminium dissolved in the $\frac{1}{4}$ litre of water; the exceptions were in two of the iron experiments. The following were the results:—

Expt.	Salt used.	Weight used, or equivalent to 1 grm. of AlCl_3 in $\frac{1}{4}$ litre H_2O .	Temperature at which dissoci- ation sets in.	Degrees c.c. of dilution required to produce de- composition with 1 grm. AlCl_3 and its equivalent.

31.	$\text{AlNH}_4\text{SO}_4 \cdot 12\text{H}_2\text{O}$	3.384	—	31260

The observations recorded in these experiments can only be considered exact from a relative point of view, as there were too many contending influences to warrant the figures being taken as individual observations. They, however, conclusively prove the following points:—The relative position that the molecules, ferric, chromic, and aluminic oxides, hold, as regards dissociation, also the laws that govern their dissociation in the presence of other salts. Thus, the alums of the ferric oxide which have been chosen to determine this point are seen to obey the chemical laws of affinity. As regards the disturbing molecule introduced, its power of substitution determines the lowering of the thermanalytic point. Also the basylous power of this atom determines the amount of decomposition. Where the trioxides alone replace the hydrogen in the acid, the molecules are held together with a force in ratio to the relative affinities, but when a second molecule comes into play, a power of determining or lowering the thermanalytic point is found in the disturbing basylous element introduced. Thus we find in the alkali group, potash acts more forcibly than ammonia; in fact, they act in this respect according their power of substitution.

As before stated, the ferric salts have been experimented upon by M. Debray*.

That experimenter says—"Je ne suppose pas que le chlorure de fer se dédouble en acide chlorhydrique et en chlorure basique, parce que l'existence de ces composés basique soluble, en tant que composés définis, en paraît peu conciliable avec le fait de leur décomposition par le filtre dans l'appareil dialyseur, ou par le sel marin qui en précipite de l'oxyde de fer pur. Il en paraît plus naturel de considérer ces composés comme des dissolutions de l'oxyde colloïdal de fer dans l'acide chlorhydrique ou tout au moins dans le sesquichlorure de fer ordinaire." Now, although M. Debray's views are in the main correct, we cannot conceive that the action of the dialyser can have anything to say to the actual condition of the solution before dialysis. Immediately that we bring a septum into play we introduce another decomposing influence to bear and entirely modify the balance of the forces at work. I hope shortly to be able to demonstrate that not only the oxides of the group, we have been considering are capable of existing in either the colloidal or crystalloidal condition, the modifying agent appearing to be, in some instances, the combined water. There can be little doubt that at elevated temperatures we get a partition of the acid, so arranged as to give an acid salt and a basic salt, and that the amount of basicity is dependent not upon temperature, which only determines a constant decomposition for each degree, but upon relative volume of water, and, when we come to extraordinary pressure, relative volatility of the stylos molecules in the presence of steam. M. Debray again says—"Le chlorure de fer se dédouble donc à une température de 70 degrés en acide chlorhydrique et en sesquioxide de fer soluble dans l'eau," &c. All through his paper he speaks of this thermanalytic point, as I will call it, as a constant quantity for the same salt under all conditions. Now this involves a principle, and I have proved this point at a given pressure is entirely dependent as regards this group (and therefore as regards M. Debray's experiments with ferric oxide) upon the relative volume of water.

So sensitive is the potassio-ferric alum that a fine amethyst-coloured crystal obtained by crystallising it at a low temperature, when placed upon the palm of the hand, first becomes white and after a short time yellow. This salt is, of course, the most sensitive of all the group mentioned in this paper.

It may be well to point out that these experiments can only determine the laws of dissociation practically to a limited extent. We must build upon them, and conceive in our mind's eye the enormous results that are attainable with the aid of unlimited time and pressure.

* "Note sur la Décomposition des sels de Sesquioxide de Fer," par M. Debray.—*Comptes Rendus*.

We are compelled to bring into play the "scientific use of the imagination" and bridge over the long gap that lies between our mimic results and those consummated in the laboratory of nature, and by this means to mentally extend our experience. The results are here, but the *modus operandi* is absolutely a sealed book.

I propose to reserve the consideration of the element silicon, more particularly in connection with the bases dealt with in this paper. This will form a second part, as I wish in an immediate one to consider the conversion of these molecules from the crystalloidal to the colloidal condition.

(To be continued).

A NEW METHOD OF QUANTITATIVE CHEMICAL ANALYSIS.*

IN comparing together the results of a large number of chemical analyses it is seen that the numbers obtained vary between 99·17 to 100·67, giving a difference of about 1·5 per cent, or, supposing a quantity of 1500 grms. of substance has been taken and the weighings carried to 0·0001 grm., a difference of 225 units. The analyses here alluded to are by no means those which would be called bad or indifferent, but are such as have been made and published by eminent chemists. It ought further to be remembered that very many analyses yield results varying from 97 to 102 per cent, instead of 100, whilst the really bad ones never see the light at all. Under ordinary circumstances slight differences do not usually affect the result of an analysis, but if it is desired to employ the sum of the substances found to control the results, an incorrect total fails to serve this purpose, as there is no means of knowing upon which of the substances the error really falls. Moreover, in many instances, only small quantities of material are available. A more accurate and improved method of analysis would admit of the employment of smaller quantities as well as effect a great saving of time and labour.

It would appear that neither the methods and processes in use nor the impurities of reagents are greatly at fault, because it is found that, when the same substance is analysed under exactly the same conditions, the results often differ. It would, therefore, appear that accuracy depends chiefly upon the manipulations, among the most dangerous of which may be mentioned decantation, the removal of substances from a filter, the ignition of the filter-paper, and the calculation of the ash; the employment of a great number of vessels may either add something to solutions or withdraw something therefrom.

Dr. H. Carmichael has proposed a very ingenious apparatus for overcoming these difficulties. His apparatus is represented in the accompanying cuts.

Fig 1, represented one-fourth of its natural size, consists of a doubly bent glass tube, with a funnel-shaped widening at one of its ends, the wider part being perforated with a large number of small holes; the other bend of the glass tube is fitted in the T-shaped tube, B C D, closed air-tight at B, by means of a vulcanised india-rubber ring; the tube is fastened in the glass plate, E F, and fitted air-tight by means of a similar contrivance to the one just mentioned; E F is covered with a cap made of vulcanised caoutchouc, while between B and C a tube is fitted laterally, bent at D, at right angles (this part is not represented in full in the cut) and fitted with a small bored vulcanised india-rubber tube closed by a spring clamp. The cap and the ring, B, should be touched with some grease. The edges of a beaker can be readily rubbed on a piece of fine grained and thoroughly smooth and level sandstone, to take off the vitreous glaze, so that a plate of ground glass may fit quite tight thereon; this having been done the cover, E F (a ground glass plate), may be fitted so tightly

that it is possible to keep in the interior of the beaker-glass as good a vacuum as in the receiver of an air-pump.

The filtering bulb, A (Fig. 2), being the most essential portion of this apparatus, its construction requires the greatest possible attention, and should be managed as follows:—

Take a glass tube having an inner bore of 2 m.m., blow at one end a thick bulb (see A, Fig. 1), flatten the bulb

FIG. 1.

at the bottom, keep this bulb so hot that the glass is only slightly soft, and while in that condition make holes in it by means of a white-hot steel wire; these holes should be close together, and not larger than 0·7 m.m. The width of the edge, a b (Fig. 2), differs according to the kind of filtering-paper which it is intended to use. For ordinary filtering-paper the width should be 3 m.m., for Swedish paper a width of 2 m.m. is sufficient; the perforated glass knob thus obtained is also ground slightly on sandstone.

FIG. 2.

FIG. 3.

FIG. 4.

The tube to which the bulb is blown should be so bent as to make the leg B somewhat longer than the leg A; the height of the bulb must not be great, that is to say, it should be sufficiently flat to carry along with the air at the end of the filtration all the liquid into the beaker. The most suitable diameter of the bulb for general use is 2·5 c.m., the number of holes ought to be 50, but a smaller number will do when the holes are connected together by means of small channels cut in the glass by means of hydrofluoric acid. The apparatus is connected with an air-pump by means of a strong india-rubber tube. The

* From "Select Methods in Chemical Analysis," by William Crookes, F.R.S., &c. London: Longmans and Co.

best air-pump is formed by the human lips, but direct experiments have proved that the power of suction of men varies from 10 to 695 c.m. of mercury, that is to say, from $\frac{1}{10}$ to $\frac{1}{100}$ of an atmospheric vacuum. When the operator cannot suck above $\frac{1}{4}$ atmosphere, or when disagreeable gases are to be worked with, the Sprengel pump or the aspirator should be used. Even when full atmospheric pressure is on, the thinnest filtering-paper will not be broken.

In order to use the apparatus the air is pumped out, water being poured simultaneously on A. The rapidity of the current thus called into play effectually removes all impurities, and the water serves also to clean the beaker. This having been done, a circularly cut piece of filtering-paper, of the same diameter as A, is pressed against A. It remains fixed there, even when the apparatus is blown into; a vacuum is again made while the filtering disc is placed in the solution of the substance to be analysed, care being taken not to let the disc touch the bottom of the vessel in which that solution is contained; as soon as the solution is filtered off from the sediment, some pure water is added, the vacuum being still maintained, after which the apparatus, with the precipitate adhering to it, is removed from the vessel in which the solution was contained, while any sediment therein remaining is transferred by careful manipulation into a previously tared crucible.

Fig. 3 exhibits the mode of the connection of the apparatus with the air-pump. The bulb is placed in the vessel, and distilled water added for the purpose of washing the

Fig. 5.

sediment thoroughly, the water running into the beaker (the vacuum being kept on) for the purpose of drying the precipitate by the current of air. This may be carried so far as to cause even gelatinous precipitates to shrink together. The spring clamp now being opened, air is admitted to the beaker, and the filtering tube removed from the crucible as well as from the cover, E F. If the operation has been properly managed, the disc of filtering-paper remains on the top of the precipitate, the upper surface of the bulb remains clean, while only a very thin and small ring of the substance adheres to the lower edge of the bulb; this substance is removed by carefully holding a piece of filtering-paper flat in the hand and pressing it gently against the bulb; turn the latter gently so as to rub all the substance on the paper, which, with the substance thus fastened to it, is thrown into the crucible. This having been done, the crucible covered with its lid, is placed in an air-bath and heated to 105° . At this temperature the precipitate becomes readily and rapidly dry, without any danger of spitting; after which the crucible

is ignited, first without the cover, until the very small quantity of paper is consumed, and afterwards with the lid on.

Although a bulb of the size above named is sufficiently large for many substances, it is preferable to have another bulb of 3.5 c.m. diameter for use with such gelatinous precipitates as alumina and peroxide of iron. Instead of the platinum crucibles in ordinary use, it is for this purpose preferable, though not indispensable, to use a platinum dish and cover, shaped as shown in Fig. 4, and weighing about 28 grms.

As the rapidity of the operations by this method makes it desirable to heat several crucibles at a time to 105° , and since this requires an air-bath with a really good gas regulator, those hitherto contrived being either of no use or somewhat expensive and too complicated, Dr. Carmichael has contrived the apparatus shown in Fig. 5. Anyone who has acquired some practice in glass-blowing may make it for his own use. Take a glass tube, 40 c.m. long and 0.6 c.m. interior diameter, bend it as shown in the woodcut so as to admit of two of the bends being placed below the false bottom of the air-bath, and the third, the vertical bend, to pass through an opening out of the bath, but so as not to touch the metal the bath is made of; at A, a glass tube of 2 m.m. interior diameter is melted on the wider tube, and shaped as shown at C; this narrower tube is branched off into two parts, each so bent as to be on a level together. At d and e holes are made in these branches in such a manner as to form small nipples towards the outside, which are next nearly closed, and then connected together by means of an india-rubber tube; the lower end of the wide glass tube is sealed, and the top opening closed with a cork, into which, through a carefully made hole, a thin and long glass rod is fitted; the cork should extend to a b, so as to exclude air. This contrivance is entirely filled with mercury, and next freed from any adhering air and moisture by heating over a spirit flame; one of the open tubes at h and g is in connection with a gas supply-pipe fitted with a tap, the other open glass tube with a burner, while the openings at d and e are so small that the gas which may pass through them is too small in quantity to heat the bath to any extent, whilst, at the same time, these openings serve to prevent the sudden extinguishing of the flame by the rapid expansion of the mercury.

The apparatus is used in the following manner:—

The bath is heated by a gas burner, until the thermometer connected with the bath indicates nearly the requisite temperature; this having been reached, the glass rod, f, is pressed down into the mercury contained in the wider tube, until the mercury at a nearly touches the part c, which should be made as straight (not rounded) as possible. The sensitiveness of this contrivance depends, of course, upon the quantity of the mercury and its adjustment of surface; but if the apparatus is made with care, according to the directions just described, the bath remains to a fraction of a degree at a constant temperature, even in a draught of air or with a change of pressure of gas. The cooling of the mercury in the narrow tubes prevents oxidation of the metal anywhere in the tube.

The following advantages are obtained by the use of the filtering bulb:—

1. The decantation of liquids is avoided.
2. The washing, ignition, and calculation of the filter-ash is entirely dispensed with. For, since the quantity of ash contained in a filter made of the best paper, and of 12 c.m. diameter, amounts to 0.0005 grm., the ash contained in a disc of filtering-paper, as used with this apparatus, would only weigh 0.00002 grm., and even if the paper were of a commoner quality it would make no difference.
3. The velocity of filtration is very great; the water flowing into the beaker in so uninterrupted a current that it appears as if no paper disc were present. When precipitates are to be filtered off, the velocity is somewhat less;

but it is then far more rapid than by the ordinary plan, and not less rapid than by Bunsen's method.

4. Since the filtering-tube dips under the fluid, no air can pass through the precipitate until it has been completely washed.

5. When a mineral has been dissolved, or when two substances have to be separated from each other, instead of, as is done by the ordinary method, placing them in a beaker to be further treated, the precipitate by this method remains in the crucible, and can be ignited directly after filtration.

6. This apparatus serves as a filtering-stand, and also as a syphon and pipette.

7. The whole apparatus may be readily kept from dust, and, if required, any gas can be readily admitted to protect a fluid to be filtered from contact with air, while a boiling solution can also be readily filtered.

8. Even so small a quantity of substance as a couple of milligrammes is sufficient for analysis. With so small quantities the entire precipitate remains fixed to the filtering disc, and may be burnt on the lid of a crucible, while any other very small portion of the substance which may adhere to any part of the apparatus may be readily removed and estimated.

9. The use of this apparatus, and the employment of small quantities of substance for analysis, occupy only about one-third of the time as compared with that required for analyses done by the ordinary plan. As an instance of the advantage of employing this method of analysis, the author quotes the following:—

A mixture was taken of magnesia, chloride of potassium, and common salt, adding thereto some hydrochloric acid so as to convert the magnesia into chloride, expelling any excess of that acid by a gentle heat. The dry saline mass was re-dissolved in water, and oxide of mercury added. The mass was next gently heated in a covered crucible, until all the mercury was volatilised, and the dry residue again treated with water and filtered by means of the filtering-tube above described, by which operation the magnesia was left behind in the crucible. It was then dried in the air-bath and ignited. The solution of the alkalis was next treated in the usual manner with chloride of platinum and alcohol, and the platino-chloride of potassium, after having been separated from the fluid by the filtering-tube, dried at 105°. The small filtering-paper disc, to which hardly a particle of the salt adhered, was removed, and the platino-chloride of potassium, first ignited by itself alone, and afterwards with the addition of the paper disc; the result being that the organic matter of the paper was sufficiently large to cause the reduction of the platinum to the metallic state. The materials left in the crucible were washed with hydrochloric acid to remove any trace of magnesia, and again ignited; the platinum in the filtrate was also reduced to metal, and the chloride of sodium present determined in the usual way, care being taken to remove and estimate the very small quantity of magnesia by means of phosphate of sodium, and to deduct the weight of the magnesia thus estimated from the weight of the chloride of sodium.

The results were as follows:—

	Quantities taken.	Quantities found.
MgO	0·0690 grm.	0·0688 grm.
KCl	0·1873 "	0·1852 "
NaCl	0·0876 "	0·0900 "
	0·3439	0·3440

It appears that the chloride of magnesium was completely converted into magnesia again, notwithstanding the small loss of this substance due to the solubility of some of it in the alkalis present; that the quantity of the potassium salt found was deficient is accounted for by the fact that the salt was only washed with dilute alcohol, without any addition of ether to lessen the solubility of the platino-chloride of potassium. The author analysed

twice a portion of a mineral, skolezite, from Scotland, taking in the first case 0·985 grm. of substance, and in the other 0·0807 grm., the result being that the percentage composition of the substance was found to be:—

	I.	II.
Silica	46·20	46·35
Alumina	26·28	26·21
Lime	9·22	9·17
Soda	5·16	5·10
Water	13·25	13·45
	130·11	100·28

In reference to the difference of the quantity of water, the author observes that the substance had been kept for several months under a desiccator. It is clear that the principle of the apparatus above described may be applied to qualitative analysis, and also in technology on a larger scale, for which purpose a porcelain plate perforated with small holes may be used with a disc of filtering-paper.

CORRESPONDENCE.

WATERING THE STREETS WITH SALINE SOLUTIONS.

To the Editor of the Chemical News.

SIR,—On page 668 of the *Journal of the Chemical Society* for October there occurs the following, taken from *Dingler's Polytechnical Journal*. I will quote the entire abstract:—

"In Hamburg a road-space of 1500 square metres was watered with 5000 lbs. of water, holding in solution 250 lbs. chloride of calcium and 250 lbs. common salt. The surface was well wetted all over. A strong smell of ink was developed, and the road did not remain moist for a perceptibly longer time than when sprinkled with pure water, nor was the formation of a crust to be observed. As the application of a sufficient quantity of salt to a large surface would be costly, and as it would require to be renewed after every heavy rain, it does not appear that the process would be of much value, even if it fulfilled the purpose intended, of absorbing water enough from the air to keep the dust laid.—C. H. G."

I am not aware that any chemist has ever disputed that strong saline solutions do not evaporate so rapidly as common water, or that a very strong solution of chloride of calcium absolutely refuses to dry up at the ordinary temperature of the atmosphere. Most chemists are, indeed, in the habit of observing how, for instance, the lump of chloride of calcium exposed in the balance-case does not become drier but wetter, and, bye and bye, liquefies in the water it absorbs from the atmosphere. The above-recorded observation, viz., that a solution containing 10 per cent of mixed chlorides of calcium and sodium dried up as rapidly as water is obviously false; and it appears rather strange that so sensible a man as Mr. Gill, who made the abstract, and who was for a long time Professor Williamson's assistant, did not append a note to it.

The untrustworthiness of many of these so-called practical facts is notorious, and is occasionally very curiously exemplified.

In the course of last summer a surveyor in one of the London districts observed that the addition of deliquescent salts *accelerated* the drying up of the water!

I wish to place on record in your columns the results of long-continued practice in Westminster—not, indeed, with the object of proving that solutions of deliquescent salts evaporate slower than water, but that the skilful application of deliquescent salts to streets is economical.

The facts are in brief these. In the summer of 1870 and 1871, the Westminster district was watered with a solution of Mr. Cooper's salts, and in both seasons the saving in expense was sufficient to pay for the patentee and to the vestry. Before the salts were used, twenty-two water carts were required to water Westminster; now eleven carts do the work, and the streets of Westminster are in a better condition than before.—I am, &c.,

J. ALFRED WANKLYN.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 9, 1871.

The only paper met with in this number bearing upon chemistry is:—

Water of the Artesian Well at Rochefort, Charente Inférieure.—Dr. Roux.—This paper contains a detailed account of several geological matters observed by the boring of the deepest Artesian well in existence, viz., 856·78 metres, while those of Grenelle and Passy (Paris) do not quite reach 700 metres. Among the notable observations recorded in this paper we notice the curious fact that the bore-rod used in this work (commenced in 1831 and finished on September 20, 1866) became highly magnetic. The well yields about 3 litres of water per second of time; the water on first reaching the surface is clear, but becomes turbid on standing, owing to loss of free carbonic acid and hence precipitation of earthy salts. The average temperature of this water is 40°; its sp. gr. = 1·0053; 1 litre contains:—Nitrogen (reduced to 0° and 760 m.m.), 17·11 c.c.; free carbonic acid (reduced at N), 2·54 c.c.; weight of these two gases together, 0·00504 grms.; free sulphuretted hydrogen, 0·00067 grms.; sulphate of soda, 2·55005; sulphate of lime, 1·80956; sulphate of magnesia, 0·46560; chloride of sodium, 0·77891; chloride of magnesium, 0·03155; chloride of ammonium, 0·00968; bromide of sodium, 0·00392; iodide of sodium, 0·00113; bicarbonate of lime, 0·11057; bicarbonate of magnesia, 0·02699; bicarbonate of protoxide of iron, 0·05666; bicarbonate of protoxide of manganese, 0·00015; arseniate of protoxide of iron, 0·00067; silicate of potash, 0·00421; silicate of alumina, 0·0020; traces of silicate of lithia, of phosphate of protoxide of iron, and of copper; organic matter (akin to crenic and apocrenic acids), 0·00067; combined water, 0·10200; chloride of calcium, 0·01720; loss, 0·01000; total, 5·98606 grms.

Bulletin Mensuel de la Société Chimique de Paris, January, February, and March (one number), 1871.

Although this small volume is published, as indicated on the title-page, for the months above named, it contains the *extraits* from the *procès verbaux* of the meetings of this society held in June, July, and August last, from which we quote the following particulars:—

Contribution to the History of the Saccharine Substances.—Dr. Mauméné.—The author states that large and well-defined crystals of the combination of sugar and chloride of sodium may be obtained by first evaporating on a water-bath a syrup which, upon 100 parts of sugar, contains 13 parts of common salt. The crystalline mass is then put into a funnel, and the mother-liquor several times poured back on the solid substance; by this operation there will be obtained in the filtrate large-sized prismatic crystals, the composition of which is $C_{12}H_{22}O_{11}NaCl + 4H_2O$. The rotatory power of the sugar thus combined is not altered, and by treating the compound with nitrate of silver the sugar is regenerated.

Influence of the Variation of Temperature upon the Mode of Decomposition of Explosive Compounds.—Dr. Jungfleisch.—Alluding to Professor Abel's explanation respecting some of the phenomena of the explosion of detonating compounds, the author states that from his experiments on this subject he is inclined to infer that the phenomena are due to the degree of temperature to which the substances are submitted. This opinion is also shared by Drs. Berthelot and Mauméné, who brought the following instances in support of their views:—When nitrate of ammonia is suddenly heated it yields, in addition to water and protoxide of nitrogen, also binoxide of nitrogen and nitrous acid; while, when upon nitrate of potash kept fused at 337° a piece of the charcoal is placed, it remains black, deutoxide of nitrogen being evolved; but a slight increase of temperature produces

a sudden decomposition attended with deflagration.

Polariscopic Rotatory Power of the Alcohols of the Amylic Series.—Dr. Ribau.—A tabulated form exhibiting the amount of rotatory power expressed in degrees of arc of the liquids alluded to.

Experiments Made with the View to Ascertain whether the Two Chlorinated Propylenes Derived from the Methyl Chloroacetol and the Chloride of Propylene are Identical.—Drs. Friedel and Silva.—As regards the main point, the authors conclude that identity exists; they incidentally observe that the action of chlorine upon propylene is considerably modified by the action of direct sunlight, since in diffused light or complete obscurity a substitution product is formed, viz., a compound, $C_3H_4Cl_2$, boiling at 92° and absorbing bromine with great avidity, forming a chlorobromide, $C_3H_4Cl_2Br_2$, boiling at 205°; in direct sunlight, chlorine is simply fixed without evolution of hydrochloric acid and formation of terchloride, $C_3H_4Cl_3$, boiling at from 122° to 124°; the chlorinated propylene derived from the chloride of propylene is similarly acted upon.

Relation Existing between Tannic and Gallic Acids.—Dr. H. Schiff.—Tannic acid is digallic acid according to the author, the gallic acid yielding by oxidation ellagic acid and another substance endowed with all the properties of tannin. This substance is termed digallic acid, $C_{14}H_{10}O_8 = 2C_7H_5O_4 - H_2O$; by the action of sulphuric acid the digallic acid is converted into rufgallic acid, which on being distilled with zinc-dust yields anthracene.

The original papers and memoirs published in this number, having been also published in other periodicals which we received at an earlier date, have been already referred to.

Les Mondes, October 19, 1871.

This number opens with the announcement of an honour conferred upon the excellent editor, who has received from the Pope the honorary degree of Doctor of Theology, a very high distinction indeed, and the more so as the Apostolic brief (of which the Latin text and a French translation are reproduced in full) intimates that this honour is conferred on Monsieur l'Abbé F. Moigno on account of his scientific labours.

Among the original papers contained in this number we notice the following:—

Unity of Matter.—Dr. Lamy.—The first instalment of a series of papers on chemical philosophy; this portion treats on the formula of acetic acid.

Use of Felspar as Manure.—Rev. Mouzot.—This paper gives a short account of the results obtained by the use of felspar where that mineral abounds and is physically so constituted as to be readily disintegrated, even when being crushed or pulverised previous to being applied to the soil. The felspar contains, as is well known, potassa, and may therefore be useful to the soil, but, as herein stated, the effect upon the vegetation is slow, and the quantity of this mineral to be used per acre rather large.

Obituary.—Under this heading we regret, in the first place, to have to record the death of Dr. Barreswil, well and deservedly known both as an excellent scientific chemist and one of the most eminent technologists of France, the author of the well-known titration process of sugar testing, and, as we learn from the brief notice, also a sound and active philanthropist. Another well-known person, whose death, at the age of 55 years, is here announced is the eminent sugar-refiner, Constant Say, the nephew of the celebrated economist, J. B. Say, and the cousin of the present Préfet de la Seine. The large sugar-refinery founded by the deceased is capable of working 280,000,000 kilos. (260,000 tons) of sugar annually; during the late siege of Paris, that place was supplied by the water from the Artesian well bored at this refinery, the yield of water of that well surpassing that of any known well of the kind. France loses in M. Say one of its most eminent industrial men, and one also who with his immense wealth did a very great deal of good.

Polytechnisches Journal von Dingler, second number for September, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

On a New Steam-Gauge.—Dr. C. V. Zenger.—After pointing out the defects of the different gauges now in use for ascertaining the pressure of steam in boilers, the author describes at great length and illustrates with engravings an instrument which, while simple in its construction, is undoubtedly free from the defects alluded to and inherent to the gauges in general use; moreover, this instrument may be arranged for vacuum gauge and for measuring the force of wind.

Continuation of the Studies on the Blast-Furnace and Iron Manufacture.—C. Schinz.—This portion contains the following sections:—Ferrie's auto-coking furnace at the Monkland iron-works; pressure of the blast; what quantity of air is really required. To be continued.

Areometrical Analysis of Beer.—A. Metz.—The description illustrated by a series of algebraical formulæ, of a process of determining in beer—after having been as much as possible deprived of the carbonic acid it contains—by means of a very sensitive areometer, the quantity of extract and alcohol it contains.

General Exhibition at Vienna, 1873.—Dr. von Schwarz-Senborn.—From this paper we quote the following particulars respecting the size, in square metres, of the following Exhibition buildings:—London

(1851), 81,591; Paris (1855), 103,156; London (1862), 186,125; Paris (1867), 441,750; intended building at Vienna, now in course of construction, 2,330,631; the length of the main building will be 950 metres, more than half an English mile.

Bayerische Industrie und Gewerbe Blatt, July, 1871.

Among the official communications published in this number we briefly notice the following:—

Establishment of a Course of Lectures on Statistics at the Royal Bavarian Ministerial Department of Commerce and Public Works.

Police Regulations on Steam-Boilers for Germany.

Petition Addressed to the German Imperial Parliament for the Introduction of a General Patent Law for Germany.

This number further contains the following original matter relating to chemistry and collateral sciences:—

Description of a Washing Apparatus.—M. Neubecker.—The apparatus herein described and illustrated with engravings appears to possess decided advantages over those in general use.

Method of Coating Metallic Objects with a Very Durable Black-Brown Varnish.—C. Puscher.—On the bottom of a cylindrical cast-iron vessel, 18 inches high, is placed a layer, $\frac{1}{2}$ inch thick, of coal-dust; upon this is placed an iron grating, and thereon are put the iron, steel, or other metallic objects intended to be coated with the varnish. The vessel, having been first closed with a well-fitting lid, is next placed on a bright coke fire, and heated for about a quarter of an hour just to incipient red heat. The vessel is then removed from the fire, and on the lid being removed, after about ten minutes, the metallic objects will be found coated very uniformly with a good and durable varnish, which resists bending, as well as a high temperature, without cracking or coming off. Very small objects, such as hooks-and-eyes for instance, are better placed along with some coal-dust in a coffee-roasting apparatus, and this turned, as is usual in the roasting of coffee, until the metallic objects have obtained the desired depth of colour and are uniformly coated with the varnish.

La Revue des Scientifiques de la France et de l'Etranger,
October 7, 14, and 21, 1871.

These numbers do not contain any original papers relating to chemistry and allied sciences.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 14,
1871.

This number contains on the title-page a polite request of the Treasurer of this Society, reminding members who have hitherto forgotten to pay their contributions to do so without delay. For the members resident in the United Kingdom, Messrs. Hopkin and Williams, 5, New Cavendish Street, London, W., are the parties to whom payment can be made; the Treasurer at Berlin is Dr. E. Schering, 21, Chausseestrasse.

The original papers contained in this number are the following:—

Calculation of the Heat Evolved by Decomposition.—A. Naumann.

On Melolonthin, a New Crystalline Nitrogen- and Sulphur-Containing Material met with in the Animal Organism.—P. Schreiner.—The substance just named has been found, along with leucin, sarkin, traces of xanthin, large quantity of urates and of oxalate of lime, in the body of the *Melolontha vulgaris*, cockchafer. The insects having been crushed and exhausted with water, this liquid is first boiled, in order to eliminate albumen compounds; after filtration, the previously somewhat evaporated and thereby concentrated liquid is precipitated with acetate of lead, again filtered, and the filtrate treated with sulphuretted hydrogen. The sulphuret of lead having been removed by filtration, the filtrate is again evaporated, so as to allow of the urates being precipitated. After having been further concentrated, the author observed, first separate crystals of leucin, and then another body, which, having been purified by re-crystallisation from its aqueous solution, was obtained in well-defined hard glossy crystals, difficultly soluble in cold, more readily so in hot water, also difficultly soluble in ordinary alcohol, and quite insoluble in absolute alcohol and ether, but readily soluble in some of the caustic and carbonated alkalies, in sulphuric, nitric, hydrochloric, and tartaric acids, and also in water containing a small quantity of ammonia; acetic acid dissolves this substance difficultly. The aqueous solution of melolonthin does not affect vegetable colours; when a solution of melolonthin is boiled along with a solution of oxide of lead in caustic potassa, sulphuret of lead is formed. The elementary composition of melolonthin is $C_8H_{12}N_2SO_2$. From 30 lbs. of the insects the author only obtained 1.56 grms. of melolonthin.

On a New Phosphorus Oxychloride, the Pyrophosphoric Acid Chloride.—A. Geuther and A. Michaelis.—After observing that of the chlorides of phosphoric acid only that of the ordinary phosphoric acid, $POCl_3$, is known, while the chlorides of the metaphosphoric acid, PO_2Cl , and that of the pyrophosphoric acid, $P_2O_5Cl_2$, are, or as far as the latter is now concerned were, unknown, the authors proceed to describe at length the method by which they succeeded in preparing the last-named compound. The preparation, which requires some caution, consists mainly in treating trichloride of phosphorus with nitrous acid. The product resulting from that reaction is rectified by distillation at from 210° to 215° , yielding a

colourless fluid which cannot be distilled without partial decomposition; the vapours of this body are akin to those of anhydrous sulphuric acid, and destroy corks; sp. gr. of the liquid, viz., $P_2O_5Cl_2$, at $7^\circ = 1.58$. Addition of water to this body decomposes it at once, heat being evolved and hydrochloric acid and ordinary phosphoric acid; the rational formula of this phosphorus oxychloride is—

Capability of Crystallisation (Krystallisations Fähigkeit) of the Ordinary Oxychloride of Phosphorus and of the Oxybromochloride of Phosphorus.—A. Geuther and A. Michaelis.—The authors have found that the ordinary oxychloride of phosphorus when cooled to -10° remains fluid, but solidifies at once when touched with a glass rod, yielding long-sized needle-shaped crystals, which melt at -1.5° . The oxybromochloride of phosphorus when cooled down below 0° also yields crystals, which melt again at $+11^\circ$.

Detection of Phenol and Bodies related thereto by means of Bromine-Water.—H. Landolt.—While engaged in testing a well-water contaminated with gas-liquor (ammoniacal water of a coal-gas work), it occurred to the author to try to detect phenol in the well-water. After having vainly tried some of the more ordinary reagents of phenol, bromine-water was employed, and observed to yield, when added in excess to a portion of the well-water, at once a yellowish-white coloured precipitate of tribromophenol, which, being insoluble, is a very characteristic, and, as found by expressly-made experiments with pure phenol, renders 1 part of that substance distinctly discernible in 437,000 parts of water. 1 part of phenol in 571,000 parts of water does not yield immediately a precipitate upon the addition of bromine-water, but after standing some time a crystalline substance, tribromophenol, makes its appearance. Phenol may be detected by the peculiar odour it has when 1 part of that body is present in 2500 parts of water. The author states that bromine-water may be used for the quantitative estimation of phenol, by collecting the precipitate of tribromophenol upon a previously-weighed filter, and drying it over sulphuric acid. The molecular weight of tribromophenol, $C_6H_2Br_3O$, is 331. In order to test whether a precipitate obtained by bromine-water is due to phenol, collect the sediment upon a filter, wash it with water, and then place the precipitate along with sodium amalgam and some water in a test-tube; after the application of a gentle heat the fluid is poured into a small evaporating basin, and sulphuric acid added, whereby the characteristic odour of phenol is emitted, and small drops of that substance may be seen floating in the fluid. As the best means to test any well-water suspected to contain traces of gas-liquor, the author advises that a larger quantity of the water should be first acidulated with sulphuric acid, then submitted to distillation, and the first quantity collected in the well-cooled receiver should be treated with bromine-water. The remainder of this very exhaustive paper is devoted to the description of the reactions which many substances, such as, for instance, aniline, toluidine, quinine, &c., yield with bromine-water.

Difference of Energy (Energie Differenz) Displayed by Phosphate of Soda Containing a Different Quantity of Water of Crystallisation.—L. Pfander.—Notwithstanding the high scientific value of this paper, treating on a subject bearing upon the mechanical theory of caloric, its contents are not suited for useful abstraction.

On Sulphobromide of Phosphorus.—A. Michaelis.—The substance referred to (discovered by Baudrimont and described by him in the *Comptes Rendus*, i., pp. 111, 517) has been studied anew by the author, who states that it crystallises in octahedra, gives off an aromatic but very pungent smell, fuses at 35° , is readily soluble in ether, sulphide of carbon, and bromide of phosphorus, and is not so readily decomposed by water as might be expected. The products of this decomposition are sulphuretted hydrogen, sulphur, phosphoric and phosphorous acids. In contact with ammonia, the sulphobromide of phosphorus is slowly decomposed in the cold, more rapidly when heat is applied; the products of this decomposition are the same as those formed by the action of water. When sulphobromide of phosphorus is prepared, according to Baudrimont's process, by the reaction of sulphuretted hydrogen upon superbromide of phosphorus, the product should be first heated with water for eliminating non-decomposed superbromide, next the substance is placed between folds of blotting-paper, and then dissolved in sulphide of carbon; the adhering water having been withdrawn by fused chloride of calcium, the sulphide of carbon leaves after its evaporation the sulphobromide of phosphorus in crystalline state.

Note on Artificial Alizarine.—R. Böttger and T. Petersen.—This paper is illustrated with a spectrum absolutely required for the due understanding of the contents.

Tension of Dissociation of Carbinamate of Ammonia.—A. Naumann.—The contents of this lengthy and highly valuable essay, elucidated by several tabulated forms, are not suited for abstraction.

Behaviour of some of the Diazo-Compounds with Alkaline Sulphites.—A. Strecker.—The following compounds are mentioned in this essay:—Combination of diazo-benzol with sulphite of potassa (formula of the salt dried at 120° , $C_6H_5N_2SO_3K$), contains 7.4 per cent of water of crystallisation driven off at 120° ; the salt is insoluble in alcohol, and very difficultly so in water; when heated with soda-lime, neither N nor aniline are evolved. Diazo-benzol-sulpho acid, forms when acted upon by sulphite of potassa a solid crystalline mass, readily soluble in boiling water, slightly soluble in alcohol; solutions exhibit acid reaction to test-paper; formula of the compound, $C_6H_5N_2SO_3$. This paper also contains some theoretical views on the constitutional formula of the diazo-compounds, illustrated by a series of complicated formulæ.

On Fore-Run.—G. Krämer and A. Pinner.—This essay is mainly written in defence of the papers published by the authors on this matter (relating to the by-products of the distillation of spirits) against the views held on this subject by Dr. Kekulé.

Chemistry at the Forty-Fourth Meeting of German Natural Philosophers and Physicists at Rostock (Mecklenburg-Schwerin), September, 1871.—V. Meyer.—This extensive paper contains a report of the proceedings of the Chemical Section of this association, which section was presided over by Dr. Schulze, Professor of Chemistry at the celebrated and ancient University of Rostock (a town of some 30,000 inhabitants). The savant just named exhibited the formation, by direct oxidation of carbon (pure), of an acid which has been provisionally named anthraconic acid, but which in many of its reactions and combinations appears to be, if not quite identical with, at least akin to mellithic acid. Owing to the importance of this subject, the author, assisted by Drs. Carstanjen and Beyer, performed at a later meeting a series of experiments which leave no doubt whatever that pure carbon may be made to yield by its oxidation mellithic acid, which, on being distilled along with soda-lime, gave benzol, and this, having been nitrated, yielded after reduction aniline. Mellithic acid occurs now and then native in brown-coal deposits. The same author describes a modification of Schlösing's method of the estimation of nitrates in potable water, which consists in the use of a peculiarly constructed flask wherein the water to be tested, after previous concentration on a water-bath, is first boiled, and a partial vacuum having been produced, a mixture of hydrochloric acid and perchloride of iron is introduced into the flask, whereby, if nitrates are present, deutoxide of nitrogen is formed, which is collected in a graduated tube made on purpose for this use by M. Giessler, at Bonn. The small quantity of air carried over with this gas is, before measuring its bulk, absorbed by a solution of protochloride of iron. It is not practicable to enter here into further details on the subjects which were *visa voce* and briefly treated of at this meeting, and are here only cursorily mentioned. The speakers all intend to publish their researches in this or other periodicals.

La France Scientifique (Ancien Cosmos), October 8, 1871.

In addition to subject-matter more particularly bearing upon and of interest to France, this number contains an excellent original paper:—

On Comparative Geology.—Dr. S. Meunier.

October 35, 1871.

This number does not contain any original papers or memoirs relating to chemistry or collateral sciences.

October 22, 1871.

The only original paper more strictly relating to exact sciences published in this number is:—

Social Philosophy of Sciences.—Dr. V. Meunier.

NOTES AND QUERIES.

Lute.—Can any of your readers acquaint me with a cheap and effective lute for wood retorts? It would have to resist the vapour of crude wood or acetic acid.—W. S.

Purifying Coal-Gas.—Can any of your readers give me the best way, on a small scale, of freeing coal-gas from impurities for laboratory use, or when heating, not illuminating, power is necessary?—M. H.

MEETINGS FOR THE WEEK,

MONDAY, NOV. 6th.—London Institution, 4. Prof. Huxley, LL.D., F.R.S., on "Elementary Physiology (II.)."
Royal Institution, 2. General Monthly Meeting.

TO CORRESPONDENTS.

A. E. Reed.—Your letter has been handed to the writer of the article. Professor Abel's address is Woolwich Arsenal.
Alpha.—Apply to Kuhlmann and Co., Lille, France, for commercial information on all compounds of baryta.

E. R. Cooley's "Cyclopedia of Practical Receipts."
J. Hiegin.—Schützenberger's "Traité des Matières Colorantes Comrenant leur Application à la Teinture," &c. 2 vols; Paris: Victor Masson. The Editor's work on the subject is in the press.

J. M. Merrick.—The paper was published in our issue of October 13, No. 620.

Dr. W. M. Watts, Marshall Hall, J. E. Wright, R. Routledge, T. Fletcher.—Received with thanks.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of **PRACTICAL CHEMISTRY**, particularly in its application to **MEDICINE, AGRICULTURE, and COMMERCE.**

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake **ANALYSES** of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE OF CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c.; of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

North London School of Chemistry, Pharmacy, &c.—

For instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has had laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871–1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 3 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

ANALYTICAL LABORATORY AND SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

THE CHEMICAL NEWS.

VOL. XXIV. No. 624.

NOTES OF

DEMONSTRATIONS ON PHYSIOLOGICAL CHEMISTRY AT ST. GEORGE'S HOSPITAL.

By S. W. MOORE.

II.

CASEIN is a variety of albumen contained in milk, not coagulable by heat, but readily with acids. To obtain it, evaporate milk to dryness, digest with ether to remove fat, dissolve in water, and precipitate with alcohol.

It is supposed that the solubility of casein is due to free alkali, and its spontaneous coagulation to the neutralisation of this with lactic acid generated by decomposition; it is not known how rennet acts when coagulating milk.

$MgSO_4$ + milk + heat, produces a pasty mass. Human milk contains about 3.0 per cent of casein; the ash of casein varies considerably. Mulder, 3.8 per cent; F. Simon, 7.0 per cent.

Cheese is impure casein, milk curdled by rennet, and pressed; flavour of cheese dependent on decomposition, the products being NH_3 , valerianic and butyric acids; old cheese is thus the most highly flavoured.

Cheese + CaH_2O_2 produces a tenacious paste.

Gelatinous Substances.

These substances do not exist in the body, but are formed by the action of boiling water. The tissues from which they are obtained are identical in composition with gelatin. Gelatin and its allies are derivatives of albumen, and are not to be obtained from any but structures serving a mechanical purpose; structures, as muscle, which are converted into force yield albumen (fibrin). Gelatin not existing in actively vital tissues does not minister to the support of the animal economy; this is proved to be correct by experiments on dogs, &c.

Gelatin is insoluble in cold water, freely soluble in hot; a solution containing 1 per cent solidifies on cooling.

Isinglass, glue, and size are modifications of gelatin. It is precipitated from solution by alcohol, $HgCl_2$, and tannin. Chlorine gas precipitates gelatin freely.

$Ca_3P_2O_4$ is readily dissolved and taken up by gelatin; this is admirably exemplified in bone.

H_2SO_4 dissolves gelatinous bodies, and converts them into glycocin (glycocoll) and leucin. KHO also produces leucin amongst other things during decomposition.

Chondrin contains less oxygen than gelatin, and differs on being precipitated by $C_2H_4O_2$, alum, and plumbic acetate.

By oxidation converted to gelatin, it is found in the permanent cartilages, also in foetal cartilage before ossification has commenced.

So-called Bases of Animal Origin.

These are mostly the result of the disintegration of force-producing tissues. They all contain N in large quantities, and are found mostly in the excreta.

Urea (CH_4N_2O); colourless, crystallises in prisms, deliquescent; contains more N than any other definite compound; it seems to be the means of carrying most of the waste N out of the system.

It occurs most abundantly in the urine; it is excreted from the blood by the urine to the extent of 1½ ozs. daily. The urine of carnivora contains it more largely than that of other animals.

Urea is metameric with NH_4CNO ; and may be formed

from it by evaporating a solution to dryness over a water-bath.

Heated to $120^\circ C$. urea melts; at a somewhat higher temperature decomposes; NH_3 and cyanate and carbonate of ammonium being formed, cyanuric acid is left in the retort; the temperature being raised, melanic acid is formed, and this, at a still higher temperature, is converted to mellon (C_9N_{13}), familiar to us as the yellow coating of Pharaoh's serpents. Biuret is obtained by heating urea at $170^\circ C$.; this body is very stable, it may be dissolved in concentrated mineral acids without decomposition.

Urea combines both with acids and bases; in one case forming such bodies as nitrate of urea, and in the other such as its mercuric salt ($2CH_4N_2O_3HgO$). Some remarkable and interesting bodies known as compound ureas are formed by substitution of various radicles for H.

Kreatin and kreatinin are compounds similar to urea; they are found in urine, the juice of muscle, &c. Kreatin, $C_4H_9N_3O_2.H_2O$, about 5 grs. in 1 lb. of flesh; cod-fish contains more than other flesh.

Kreatinin, $C_4H_7N_3O$, occurs with kreatin, but may be formed by boiling the latter substance with HCl. Sarkosin and guanin are similar but unimportant bodies.

There are three bodies which are closely allied in properties forming homologous acids when acted on by nitrous acid; these are glycocin, alanin, and leucin. Glycocin, or glycocoll, the result of boiling gelatin in H_2SO_4 , gives glycolic acid. Alanin gives lactic acid.

Leucin (obtained by fusing cheese with KHO, dissolving in hot water, supersaturating with $C_2H_4O_2$, filtering, evaporating mother-liquor, and crystallising) gives leucic acid.

Glycocin, $C_2H_5NO_2$	Glycolic, $HC_2H_3O_3$.
Alanin, $C_3H_7NO_2$	Lactic, $HC_3H_5O_3$.
Leucin, $C_6H_{13}NO_2$	Leucic, $HC_6H_{11}O_3$.

NOTE ON THE CHROMIUM OXYCHLORIDE DESCRIBED BY HERR ZETTNOW

IN

"POGGENDORFF'S ANNALEN DER PHYSIK UND CHEMIE,"
No. 6, 1871.

By T. E. THORPE, F.R.S.E.

IN the above-mentioned number of *Poggendorff's Annalen*,* Herr Emil Zettnow describes an oxychloride of chromium to which he assigns the formula $Cr_2Cl_4O + 4CrO_3$. It is obtained by heating potassium chlorochromate—

with strong sulphuric acid, and after a somewhat tedious course of preparation appears as a brownish black, brittle, amorphous substance, exceedingly hygroscopic, and giving up its chlorine with great ease. Herr Zettnow's analytical results and the numbers required by his formula are—

	Found.	Calculated.
Cr	47.28	47.23
Cl	22.31	21.42
O	—	31.35
		100.00

In the *Proceedings of the Literary and Philosophical Society of Manchester* for November 2, 1869† I described a solid chromium oxychloride obtained by simply heating chromyl dichloride in a sealed tube, and which, on completely freeing from the latter body, "appears as a black non-crystalline powder, which, when exposed to the air, rapidly deliquesces to a dark reddish-brown syrupy liquid which smells of free chlorine (*loc. cit.*). These properties,

* See also *CHEMICAL NEWS*, vol. xxiv., p. 133.

† *CHEMICAL NEWS*, vol. xx., p. 245. *Zeitschr. für Chemie*, Jan. 1870, p. 95.

it will be observed, are precisely those which Herr Zettnow describes as belonging to his chromate of chrom-oxychloride. On analysis it yielded as the mean of four determinations made on different preparations:—

Cl 21.06
Cr 48.91

numbers approximating to those obtained by Herr Zettnow. To this compound I was induced, for reasons which I need not here reproduce, to give the formula—

and to regard it as the chromium term of a series of salts a few members of which had already been described by Peligot, viz.:—

Potassium chlorochromate	$\text{ClCrO}_2\cdot\text{O}\cdot\text{K}_2\cdot\text{O}\cdot\text{CrO}_2\text{Cl}$
Sodium	$\text{ClCrO}_2\cdot\text{O}\cdot\text{Na}_2\cdot\text{O}\cdot\text{CrO}_2\text{Cl}$
Ammonium	$\text{ClCrO}_2\cdot\text{O}\cdot(\text{NH}_4)_2\cdot\text{O}\cdot\text{CrO}_2\text{Cl}$
Magnesium	$\text{ClCrO}_2\cdot\text{O}\cdot\text{Mg}\cdot\text{O}\cdot\text{CrO}_2\text{Cl}$
Calcium	$\text{ClCrO}_2\cdot\text{O}\cdot\text{Ca}\cdot\text{O}\cdot\text{CrO}_2\text{Cl}$

The above formula for the chromium chlorochromate requires—

Cl 21.86
Cr 48.54

From the close agreement in the analytical results and correspondence in their physical properties, I am inclined to believe that Herr Zettnow's compound is identical with mine. Potassium chlorochromate heated with sulphuric acid yields, among other products, chromyl dichloride, and, doubtless, Herr Zettnow's compound has been derived from this body under circumstances analogous to those in which I have already operated.

As my little notice on this matter has evidently not come under Herr Zettnow's observation, he may be interested to learn that the six or seven weeks time which he finds necessary to give to the preparation of this rather uninteresting compound may be considerably shortened by simply heating the chromyl dichloride in a closed vessel, when, in a few minutes, it may be transformed in any wished for quantity almost completely into the chromium chlorochromate and free chlorine.

ON THE ESTIMATION OF SULPHUR BY BARIUM.

By R. GLENDINNING and A. EDGER,
Newcastle-on-Tyne.

OWING to some delay we did not receive the *CHEMICAL NEWS* of the 13th ult., until a week after its publication, and were thereby late in seeing the remarks of Messrs. Teschemacher and Smith upon our paper on the above subject.

They quote from our article, "We attribute this (film) to sulphate of iron." Now the above quotation taken by itself is calculated to destroy the meaning of our explanation of the cause of the "film" of sulphate of baryta.

To save our readers the trouble of reference, we beg to lay before them the passage to which Messrs. Teschemacher and Smith have taken particular exception:—

"The fact that sulphate of baryta is gradually deposited when the clear filtrate and washings are allowed to stand for some time, will admit of a different explanation than that offered by them, that (sulphate of barytes is noticeably soluble in hot and but moderately diluted hydrochloric acid). We attribute this to sulphate of iron, which is invariably carried down with the sulphate of barytes, and which appears on treatment with hydrochloric acid after the precipitate has been freed from chloride of barium."

The natural inference to be drawn from the above remarks by any one at all familiar with chemical reactions, would be that, on the sulphate of iron in the acid washings

coming in contact with the chloride of barium in the filtrate, a precipitation of sulphate of barytes would result.

We did not deem it necessary to take up the valuable space of the *CHEMICAL NEWS* by entering into such superfluous explanations. The object of our paper was simply to state facts which our long experience in the testing of sulphur ores had brought under our notice, not to excite the animosity of Messrs. Teschemacher and Smith. It is to be regretted that our having ventured to disagree with these gentlemen should have caused them to show their disapproval in such strong terms.

REPORT ON THE MOLECULAR DISSOCIATION BY HEAT OF COMPOUNDS IN SOLUTION.*

By CHARLES R. C. TICHBORNE, F.C.S., M.R.I.A., &c.

(Concluded from p. 213).

ADDENDUM.

On the Transition of Compounds from the Colloid to the Crystalloid Condition.

IN part I of this report reference has been frequently made to the fact that ferric, chromic, and aluminic oxides and their compounds are capable of taking the colloidal form. It may be necessary to explain what the author means in reference to this point.

Now there is a peculiar character of crystallisation discerned in minerals which is always indicative that the constituents had been previously in this colloidal condition, and had afterwards become crystalline. In most cases, this change proceeds from assimilation of water of crystallisation, but not necessarily so. The characteristic which I wish to specify is where the crystals radiate from a centre and form in the aggregate what may be termed the radial spherical system. It includes many of the forms technically known as nodular, mammellated, botryoidal, and reniform masses. Such minerals are formed in most cases from aqueous solutions, which had evidently been at one period under the dissociating influence of heat. The iron, manganese, and lime minerals, and also the zeolites, exhibit these peculiar forms most strikingly, but none more so than that beautiful mineral wavelite. The mode by which this form of crystallisation is produced cannot be more strikingly exhibited than by an organic salt which I described some years ago, viz., chlorate of quinia. Although this substance is organic the formation can be more easily observed in such a case than in the minerals, where time and pressure are such important elements that it is not capable of experimental verification.

If a very strong and boiling solution of chlorate of quinia be allowed to cool, we find that when the solution arrives at a temperature of about 47° C. the salt begins to fall out, but not in a crystalline form. On examination with a magnifying lens it will be seen that it is separating in globules, which, from the natural laws of fluids floating in fluids, take the shape of perfect spheres. There is generally one large sphere surrounded by a number of small ones which frequently coalesce, showing that they are simply obeying the ordinary laws of gravity of mass. The colloid spheres after some time become crystalline. Thus, starting from the centre, crystals shoot out to the periphery and produce those elegantly arranged masses so well shown in wavelite. Indeed, the salt chlorate of quinia, when viewed in the vessel in which it is crystallised, bears such a wonderful resemblance to that mineral that this salt might be aptly termed organic wavelite. If we make a section of one of the globes of wavelite, we shall generally find that

* Read before the Royal Irish Academy, April 24, 1871.

outside of the general mass is a layer of crystals which are evidently a distinct supplementary formation. This would seem to be a further formation of the mineral after it had ceased to be deposited in the colloidal spheres, or, perhaps, the alteration in character of the mineral from a change in the temperature at which the mineral was no longer deposited in its colloidal condition. Two conditions of deposition are likewise observed in the organic salt. This outside layer generally forms but a small proportion to the mass of the sphere in the mineral. The conversion of the compounds of the trioxides into the colloidal state on heating their solutions is rendered probable by their slowness in crystallisation, and from the spherical form of crystallisation so frequently observed in the minerals of this group. Many of their salts also exhibit this phenomenon. Thus, if a solution of hydrated ferric chloride is crystallised by slow evaporation, distinct and well-formed crystals of the salt are produced; but if it is evaporated by heat to a strong solution to such a point that there is a limited amount of available water, it crystallises by reabsorption of atmospheric moisture in the spherical form,* from the radii striking out to what must evidently have been the periphery of colloidal separations.

ON THE ESTIMATION OF ANTIMONY, AND THE

SEPARATION OF ANTIMONY FROM TIN, FROM ARSENIC,
FROM TIN AND ARSENIC, AND FROM THE OTHER
METALS, BY MEANS OF A NEW PRECIPITATING
REAGENT OF ANTIMONY.

By HUGO TAMM.

(Concluded from p. 209).

Estimation of Antimony in Antimony Regulus.

TWENTY grs. of the metal finely powdered are attacked by hydrochloric acid, to which powdered chlorate of potash is added little by little until all the metal is taken up. Aqua regia might be used instead of the former mixture, but chemists could not be warned too much against using this double acid when the gallic acid process is employed.

In these operations, antimony is of course dissolved in the state of perchloride, which is, even in solution, a very volatile substance.

By reason of a phenomenon not well studied yet, it is only with an extreme difficulty that the nitro-chlorinated fumes evolved by aqua regia can be made to leave perchloride of antimony, with which they appear to form a combination remarkable for its stability. Indeed, it is almost impossible to free perchloride of antimony from these fumes without volatilising part of it.

By using chlorate of potash, on the contrary, the solution of perchloride of antimony obtained can be freed from the chlorine evolved with the utmost facility and at a low temperature. Besides, the chloride of potassium formed during this operation combines with perchloride of antimony, and gives stability to this compound, which can be handled at a much higher temperature than the simple chloride, without incurring the risk of any loss of antimony by volatilisation.

As soon as all the antimony is dissolved, and the last traces of chlorine are disengaged, powdered iodide of potassium is added, little by little, until no more iodine is evolved. If it is necessary, a little excess of hydrochloric acid is added to assist the reaction.

This operation can be conducted with safety at a temperature near that of the boiling-point of the liquor. At that temperature iodine is freely volatilised, and any loss in antimony is completely prevented by the presence of chloride of potassium.

* $\text{Fe}_2\text{Cl}_6\cdot\text{H}_2\text{O}$ (Mohr).

As soon as a slight excess of iodide of potassium dissolves in the clear liquor without deepening its colour or evolving iodine, the reduction of the perchloride of antimony is complete. If the solution is too acid, it is evaporated to the proper degree of concentration, and it is then precipitated by gallic acid.

All the metals alloyed with antimony will be found in the liquor separated by filtration from gallate of antimony, where they can be separated from each other and estimated by the usual methods. Iron forming an exception, it must be estimated in a special operation,—in that in which the alkaline metals which might be alloyed with antimony would be determined.

Estimation of Antimony in Antimonial Fumes, and in Artificial and Native Oxides of Antimony.

The estimation of antimony in native oxides of antimony has become of late an important operation, owing to the discovery of large deposits of this substance, constituting the best ores of antimony known to metallurgists.

The native oxides of antimony, as well as the calcined oxides of antimony, are generally insoluble in hydrochloric acid, and formerly it was necessary to fuse them first with carbonate of potash, or a mixture of carbonate of potash and sulphur in order to dissolve them.

But this operation, one of the most tedious in analysis, has been entirely superseded by the method which I am going to describe, and which answers admirably the purpose.

Iodide of potassium not only reacts on solutions of perchloride of antimony, but, in presence of hydrochloric acid, it reduces both antimonious and antimonie acid to the state of teroxide of antimony soluble in hydrochloric acid, with formation of terchloride of antimony. Iodine is evolved.

This interesting reaction takes place according to the following formulæ:—

Consequently to analyse or to assay any of the oxides of antimony, whether artificial or native, they are first of all finely powdered; 20 grs. of the oxides are mixed with hydrochloric acid; the mixture is heated, and iodide of potassium is added until no more iodine is evolved, this being the best indication that all the oxide of antimony is dissolved. The solution is filtered in order to separate it from any insoluble residue, and the filter is washed with dilute hydrochloric acid; this solution is then evaporated to the proper point and precipitated by gallic acid.

The complete analysis may be conducted on 50 grs. in the same way as above, and native oxides will be found in general remarkably free from arsenic and from metals.

Fifty grs. more are dissolved by hydrochloric acid and iodide of potassium, and the solution is precipitated by sulphuretted hydrogen in order to estimate iron and the earthy metals.

When, as frequently happens, the ore to be tried is formed of a mixture of sulphuret of antimony and of oxide of antimony, the ore is dissolved first in hydrochloric acid, the solution is poured off the insoluble residue, which is next dissolved in hydrochloric acid and iodide of potassium. The two solutions mixed together are evaporated and precipitated by gallic acid.

Oxides of antimony, from whatever source they come, being dissolved by hydrochloric acid or by a mixture of hydrochloric acid and iodide of potassium, the estimation of antimony in these compounds has thus become one of the most simple operations in analysis.

Separation of Antimony from most Metals.

Gallic acid effects with the greatest perfection the separation of antimony from most metals, when the

general ways of proceeding and the general precautions as above explained are applied to the analysis of alloys and compounds of antimony. The immense advantage of the gallic acid process is, that by its means antimony is both separated and estimated in one operation, while by the sulphuretted hydrogen process the sulphide of antimony obtained in most cases is of an unknown composition, even when free from other metals, and that it cannot be used for the direct estimation of antimony.

However, sulphuretted hydrogen must remain the standard precipitating reagent of antimony, and its standard separating reagent from all the metals which are not precipitated by sulphuretted hydrogen; and in the analysis of alloys and other compounds of antimony the simultaneous use of both methods ought to be recommended.

By the gallic acid process antimony is separated and estimated in the state of bigallate of antimony, while all the other metals are left in the solution, from which they may all be precipitated (with the exception of iron) either by sulphuretted hydrogen, sulphide of ammonium, or by the successive use of both reagents.

By the sulphuretted hydrogen process, on the contrary, iron which cannot be estimated properly by the gallic acid process, and all the metals not precipitated by sulphuretted hydrogen, remain in solution, so that by the judicious use of these two methods most perfect and elaborate analyses of antimony compounds may be obtained.

It would be tedious, and, on the whole, useless, to describe with more detail the separation of antimony from each metal, but it is, on the contrary, most important to know how the gallic acid method answers for the separation of antimony from the metals which are precipitated with antimony by sulphuretted hydrogen.

Separation of Antimony from Silver, Mercury, Bismuth, Cadmium, Copper, and Lead.

Whenever a clear solution of chlorides can be obtained after the successive use of hydrochloric acid, chlorate of potash, and iodide of potassium, and providing the solution is not too acid, it may be successfully treated by gallic acid, and antimony will then be separated with the greatest perfection from either silver, mercury, bismuth, cadmium, copper, lead, or from a mixture of these metals.

When, on the contrary, the quantity of silver or lead is so great that the compound cannot be dissolved by hydrochloric acid and chlorate of potash, another method must be resorted to, the sulphide of ammonium process being the best.

In alloys or compounds of antimony and copper no better method than the gallic acid process can be used, especially when there is more antimony than copper. The separation is quite perfect. In the liquor separated by filtration from bigallate of antimony, copper may be precipitated in the state of sulphocyanide by means of the copper reagent* and any other metal may be estimated afterwards.

Type metal and other alloys of antimony with lead and other metals can be most successfully analysed by the gallic acid process.

The alloy reduced to a fine state of division is attacked by hydrochloric acid and chlorate of potash; the produce, which at this stage of the operation may not be clear, but milky, is reduced by iodide of potassium; a clear liquid is obtained, which is precipitated by gallic acid. The separation is complete, and in the solution lead may be thoroughly precipitated by sulphuric acid, and afterwards any metal which may be present.

I will not insist further on the analysis of compounds of antimony and silver, mercury, bismuth, cadmium, copper, and lead. From the general statements contained in this paper, it must be quite evident that whenever it is possible to use it all the advantages are in favour of the gallic acid process.

Separation of Antimony from Arsenic.

The separation of antimony from arsenic, which was, until lately, a delicate as well as a difficult separation, has been wonderfully simplified by the application of the gallic acid method to the separation of those two congener substances.

Iodide of potassium, which, in presence of hydrochloric acid, reduces peroxide of antimony to the state of teroxide with evolution of iodine, reacts in a similar manner on arsenic acid, which it reduces to the state of arsenious acid—

So that whenever arsenic and antimony co-exist in an hydrochloric solution, by the addition of a sufficient quantity of iodide of potassium, an hydrochloric solution of terchloride of antimony and of arsenious acid is obtained. Now this is very fortunate, for the separation of antimony from arsenic by gallic acid is especially neat and easy when antimony existing as terchloride, arsenic is present in the state of arsenious acid.

The chief products containing both antimony and arsenic which it is important to analyse are compounds of oxides of antimony with arsenious or arsenic acids, the mixtures of sulphurets of antimony and arsenic obtained in the course of a great number of mineral analyses, and lastly alloys of antimony and arsenic. The mixture of oxides of antimony and arsenic has only to be treated by hydrochloric acid, to which iodide of potassium is added until no iodine is evolved, to give hydrochloric solutions of teroxide of antimony and arsenious acid quite ready to be precipitated by gallic acid. The mixture of sulphurets, or the alloys of antimony and arsenic, after being reduced to a very fine state of division, are attacked by hydrochloric acid and chlorate of potash. The solution is freed from chlorine by heating for a short time at a low temperature, and then reduced by means of a slight excess of iodide of potassium until no more iodine is evolved. If the solution is too acid, it is evaporated until crystals of iodide of antimony begin to appear, and it is then precipitated by gallic acid.

The filtering and washing of the precipitate of bigallate of antimony are conducted exactly as in the previous separations.

Antimony is estimated either as bigallate or as tersulphide, and arsenic is precipitated from the filtrate by means of sulphuretted hydrogen in the state of tersulphide.

When there is more antimony than arsenic in the compound to be analysed, 20 or 25 grs. is a sufficient quantity to operate upon; but when there is a great deal more arsenic than antimony, it is advisable to operate upon 50 grs.

There is no peculiarity to be noticed in the separation of antimony from arsenic by the gallic acid process. The general considerations given above apply here, and with a little care and a little experience very accurate results are obtained.

Separation of Antimony from Tin.

Iodide of potassium has no reducing effect upon hydrochloric acid solutions of perchloride of tin, but when an excess of iodide is introduced in the solution a double decomposition takes place, and the liquor consists of an hydrochloric acid solution of periodide of tin. This reaction is important, as experience has proved that gallic acid separates much more easily teroxide of antimony from biniodide of tin than from the bichloride of the same metal.

The most important compounds containing antimony and tin are the alloys of those two metals, and, in general, 20 or 25 grs. of the alloy previously reduced to a very fine state of division are sufficient to conduct successfully the separation. The alloy is dissolved as usual in a mixture of hydrochloric acid and chlorate of potash.

It is in this instance more especially that the use of

* CHEMICAL NEWS, vol. xxiv., p. 91.

aqua regia should be forbidden; bichloride of tin, like perchloride of antimony, retains powerfully the fumes evolved by aqua regia, and it is not possible to drive off those fumes without volatilising a considerable quantity of tin and antimony.

The solution in hydrochloric acid and chlorate of potash, freed from chlorine as usual, is reduced by iodide of potassium until no more iodine is evolved. When this is done a quantity of iodide of potassium, equal to about half the quantity of iodide employed for the reduction of the liquor, is added in excess, and the mixture is heated for a short time. It is a judicious addition of a sufficient quantity of this salt in excess which decides a successful separation of antimony from tin by gallic acid. After the solution has been brought to the proper degree of concentration, gallic acid is added and afterwards water.

When the former series of operations has been properly conducted, bigallate of antimony settles very rapidly in the liquor. When, on the contrary, the operation has been badly performed, bigallate of antimony is mixed with peroxide of tin, and it remains in suspension in the liquor without settling. In this case the liquor should be rejected as unfit for a neat separation.

When, on the contrary, bigallate of antimony settles rapidly, the operation can be depended upon, and the filtering and washing of the precipitate are proceeded with. Antimony is estimated either as bigallate or as tersulphide, and tin is precipitated from the filtrate by sulphuretted hydrogen in the state of bisulphuret of tin, which, on calcination at a high temperature, gives pure peroxide of tin.

The separation of tin and antimony by gallic acid is not quite so simple as the separation of antimony from arsenic by the same process, for the reason that tin cannot be easily reduced from the state of perchloride to that of protochloride. But if it were possible to effect easily this transformation, the separation of antimony from tin would then be the easiest separation that can be effected by means of gallic acid. However, such as it is, the separation is very neat, and requires only a little attention and experience to be quite perfect.

Separation of Antimony from Arsenic and Tin.

Although gallic acid separates well antimony from arsenic, and antimony from tin, it does not follow that gallic acid should separate properly antimony from arsenic and tin. Still, it is a positive fact gallic acid separates, and separates well, antimony from arsenic and tin. The separation is conducted exactly as a separation of antimony from tin.

The three metals are dissolved by hydrochloric acid and chlorate of potash respectively in the state of perchloride of antimony, arsenic acid, and bichloride of tin. On addition of iodide of potassium until complete evolution of iodine, antimony is reduced to the state of terchloride, arsenic to that of arsenious acid, and, on addition of a proper quantity of iodide in excess, tin is transformed into biniodide of tin.

When the solution thus obtained has been brought to the proper degree of concentration, and properly freed from the excess of hydrochloric acid which it might still contain, it is precipitated by gallic acid, water is added, and the remaining part of the operation is conducted as usual.

The best indication that the separation is perfect is the fact that bigallate of antimony settles rapidly.

In this instance, as in the case of the separation of antimony from tin by gallic acid, if bigallate of antimony refuses to settle rapidly, it is an indication that it is mixed with peroxide of tin, and the liquor should be rejected at once as useless.

In the filtrate, tin and arsenic should be precipitated by sulphuretted hydrogen in the state of sulphides, and this mixture should be separated by one of the approved methods.

Remarks.—After the separation of antimony from arsenic, from tin, or from arsenic and tin, the bigallate of antimony obtained and used for the estimation of antimony should be dissolved in weak hydrochloric acid and precipitated by sulphuretted hydrogen, when antimony ought to be precipitated after each separation in the state of that fine orange-coloured sulphide so well known.

Final Considerations.—Although the separation of antimony from arsenic and tin is a very simple one, when the gallic acid process is applied to it, I cannot say that I have succeeded in solving that most difficult of problems, an easy separation of antimony, tin, and arsenic.

I have signally failed there, where so many have failed before me, for the reason that a mixture of antimony and arsenic does not behave with reagents as a mixture of antimony and arsenic, but, on the contrary, as a new metal, *stibarsenicum*, which possesses peculiar properties and requires special reagents.

A mixture of tin and arsenic also presents all the appearance of the new metal *stannarsenicum*; and a mixture of tin and antimony all those of the new metal *stannantimonium*.

But the properties and the reagents of those three new metals being well studied and well known, it might appear that those of a mixture of the three would soon be mastered.

It is not so, however, and their mixture possesses all the characters of a new metal, *stannarsenicantimonium*, differing in properties from *stibarsenicum*, from *stannarsenicum*, from *stannantimonium*, from arsenic, from antimony, and from tin.

It is not, therefore, surprising that the problem of the separation of antimony, arsenic, and tin should be so difficult to solve.

The solution of this problem, however, will be found in the use of powerful reagents, capable of destroying the strange affinities exhibited by the three metals, and I have every reason to believe that organic acids will be the means of accomplishing this object.

ON THE COLOURS OF METALS.*

By Professor C. A. SEELY.

Of all the metals, two only, gold and copper, are distinctly coloured. When nicely polished the surfaces of all metals become nearly perfect mirrors, reflecting almost all the light, whatever be its tint, which falls upon them, and the chemically clean matte surfaces of all metals except gold and copper appear white to the eye. Yet the white light from such surfaces is invariably contaminated with a small amount of coloured light, and this coloured light is without doubt the result of a normal and ordinary decomposition of the incident white light. If the greater part of the incident white light were in the same way decomposed, the metals, instead of appearing to us white, would shine with splendid colours. The colours of natural objects are always mixed with white light, that is, the white light falling on the surfaces of natural objects is never completely decomposed, and in this regard the case of the metal shows a difference in degree and not in kind. To the eye of the scientist, then, all the metals may be coloured; the colours are ordinarily invisible simply because they are diluted or overpowered by the white light with which they are mingled. With the explanation thus given I assume in this paper that all metals are coloured.

The most satisfactory method of rendering the colours of metals apparent heretofore proposed consists in repeatedly reflecting a beam of white light from the metallic surface under examination. A convenient arrangement is two parallel plates of the metal, between which the

* Read before the New York Lyceum of Natural History.

light is reflected from one to the other at a small angle of incidence.

At each incidence the white light is partially decomposed, and if the number of incidences be sufficiently multiplied, all the white light will have disappeared, and only the pure coloured rays be visible. In this way the colours of most of the metals have been exactly determined. The actual experiment, however, is not a very brilliant one, inasmuch as the larger part of the light with which it begins is lost by gradual diffusion; especially the coloured light is so lost, probably for the reason that the decomposition of the white light takes place within the reflecting surface.

Another method of developing the true colours of metals has recently occurred to me, and it is the main purpose of this paper to describe it. I present first a few theoretical considerations.

When white light is decomposed by a coloured body, the reflected coloured ray is complementary to that part of the white light which is transmitted or absorbed; if a coloured body be seen both by reflected and transmitted light, the colours so seen should be complementary, or an approach to being so.

These statements seem to have many exceptions, as, for example, the coloured transparent salts of metals show the same colour by reflected as by transmitted light. But I am persuaded that a careful discussion of the case would show that such exceptions are not well taken, and that this apparent discrepancy with the statements may be consistently explained away; thus it may be shown that the supposed reflected light of the exceptions is really a part of the transmitted light which has been returned by internal reflection; such mixture of the transmitted with a reflected light implies a considerable degree of transparency of the substance under test. The lustre and whiteness of metals have a close relation to their opacity and density; perhaps the relation is that of effect and cause. If the opacity and density of metals be progressively decreased, the optical metallic character will in the same ratio be diminished; the true colour by reflected light would become brighter and freer from white light till it come to be contaminated with more and more of the returned transmitted light. Such changes are beautifully exemplified by the gradual additions of a solvent to fuchsine or other aniline colours in crystals. Aniline colours, Prussian blue, indigo, carmine, and all other dye-stuffs which have very great tinctorial powers, have the metallic lustre, and their colour by transmitted light is nearly complementary to that by reflected light.

In their relation to light I suggest that metals are closely analogous to those dye-stuffs which show a bronzed surface by reflected light. Metals are more perfectly bronzed because their opacity and density are greater, or, in other words, their tinctorial powers are greater.

It will be seen that the above theory requires for its demonstration a transparent diluent or solvent of metals, which shall have no chemical action on them. Such a solvent, for a few of the metals, is anhydrous liquid ammonia. If this menstruum be gradually added to the silver-white alkali metals, the whiteness disappears, is replaced by copper-redness, which at last gives place to the blue of transmitted light. The changes of tint in this case from copper-redness to the transparent blue may be exactly repeated by treating pure aniline blue with alcohol. The alkali metals are then copper-red in reflected light, and by transmitted light blue. In this connection, the fact that the salts of copper are blue is, perhaps, of some significance.

The solution of metals without definite chemical action is almost a new idea in chemistry. Faraday made the first approach to it by showing that the colour of ruby glass is due to metallic gold; and it received a final and definite shape in a demonstration of the solvent properties of anhydrous liquid ammonia, which I made at the late Troy

meeting of the American Association for the Advancement of Science.

The tinctorial power of metals appears to be vastly greater than that of any known dye-stuff, and the colours they should yield are very brilliant. There is reason, then, to hope that these facts about metals may some day receive some useful application.

ON THE OXYCHLORIDES OF ANTIMONY.*

By WILLIAM CARLETON WILLIAMS,
Student in the Laboratory of Owen's College.

PHOSPHORUS oxychloride, POCl_3 , having been prepared by heating together one molecule of phosphorus pentoxide with three of pentachloride, it appeared not unlikely that a similar reaction might occur with antimony giving rise to the missing oxychloride corresponding to the phosphorus compound above mentioned.

The following investigation was undertaken at Dr. Roscoe's request, with the view of elucidating the above reaction, as no oxychlorides derived from the pentachloride have as yet been described.

A mixture of one molecule of antimony pentoxide prepared by heating the pentachloride with water with three molecules of the pentachloride, was heated for some hours in sealed tubes to 140°C . On opening the tube after cooling, it was found to contain, besides unchanged pentachloride and pentoxide, two distinct solid crystalline compounds. When the pentoxide prepared by the action of nitric acid on the metal is heated with the pentachloride in a similar way no oxychloride is formed.

One of these fuses at 85°C . to a clear yellowish liquid, whilst the other, produced only in small quantities, is found adhering to the top of the tube in minute yellowish crystals, which fuse at a higher temperature. In order to obtain the first of these substances in a pure state it is sufficient to place the tube upright in a vessel of water at 90° with the empty end downwards; the fusible oxychloride then melts and collects as a perfectly clear yellowish liquid. After cooling, the tube is opened, and the small quantity of residual pentachloride having been poured off, the solid mass is dried on a porous plate over solid caustic potash *in vacuo*. The oxychloride thus obtained is a perfectly white crystalline substance, exceedingly hygroscopic, so that when exposed to the air for a few minutes it becomes a pasty mass, which rapidly changes to a liquid. It readily dissolves in an aqueous solution of tartaric acid, whilst it is decomposed by water and is perfectly insoluble in carbon disulphide. The melting-point of the substance is 85°C . as a mean of well agreeing determination made with four different preparations. When heated in a retort until it boils, chlorine gas is evolved, whilst pentachloride and trichloride of antimony distil over, a residue of antimony pentoxide remaining in the retort.

A modification of Rose's well-known method of precipitation, first as insoluble antimoniate of soda, and then as antimony sulphide, was employed for the determination of the antimony; the precipitated sulphide was (1) oxidised to Sb_2O_4 either by treatment with pure fuming nitric acid or by heating with from 10 to 20 times its weight of pure mercuric oxide, and (2) the sulphide was completely reduced to metallic antimony by heating gently in a current of hydrogen until sulphuretted hydrogen ceases to be evolved. In the estimation of chlorine it was found that when silver nitrate is added to a solution of an antimony oxychloride acidified by nitric acid, a small trace of antimony is invariably carried down with the silver chloride. In order to free the precipitate from antimony, the silver chloride is first heated gently in a current of hydrogen, when the silver is reduced, and on

* Read before the Manchester Literary and Philosophical Society, October 17th, 1871.

stronger ignition the whole of the antimony is volatilised as the hydrogen compound. Thus 1.277 grms. of an alloy, containing 2.5 parts of antimony to 97.5 parts of silver, was found to lose on heating in hydrogen 0.0321 grm., corresponding to 97.48 per cent of silver.

The accuracy of each of the above methods was tested by determining the percentage of antimony and chlorine in pure antimony trichloride, the results agreeing closely with each other and with the theoretical composition. The objection to Schaeffer's method of decomposing the oxychloride by boiling with a solution of sodium carbonate is, that the precipitated oxide of antimony being in a very finely divided state, a portion of it is very apt to pass through the filter on washing.

The simplest formula which agrees with the analytical results is $\text{Sb}_2\text{Cl}_3\text{O}_5$, or three molecules of pentachloride in which two of chlorine are replaced by one of oxygen.

	Calculated.	Found.
Sb_2	43.39	43.46
Cl_{13}	54.71	54.75
O	1.90	—
	100.00	

That this is a definite compound and not a mere mixture of pentoxide and pentachloride ($\text{Sb}_2\text{O}_5 + 1.5\text{SbCl}_3$) is evident from the fact that the latter substance is not dissolved out by washing with carbon disulphide. The calculated percentage of pentoxide contained in this compound is 7.68; on heating 2.517 grms. of the oxychloride in a tube retort a residue of 0.1799 grm. of pentoxide remained, corresponding to a percentage of 7.14.

The second oxychloride formed by heating the mixture of one molecule of pentoxide and three of pentachloride is produced only in small quantities as yellowish crystals. To obtain it in the pure state, that portion of the tube in which the substance is found is cut off, and after the tube has been re-sealed it is placed in a slanting direction in a vessel containing water heated from 85° to 90° . The $\text{Sb}_2\text{Cl}_{13}\text{O}$ melts and runs down, leaving the other less fusible oxychloride behind; this is then dried on a porous plate *in vacuo* over solid caustic potash. Two determinations showed that the melting-point of this substance is 97.5°C .

The simplest formula agreeing with the analytical numbers is $\text{Sb}_2\text{O}_4\text{Cl}_7$, or three molecules of antimony pentachloride in which 4 atoms of oxygen replace 8 of chlorine.

	Calculated.	Found.
Sb_3	53.93	53.89
Cl_7	36.62	36.58
O_4	9.44	—
	100.00	

From the above results it is clear that the simple phosphorus oxychloride is not reproduced under similar circumstances in the antimony series, but that this element in agreement with its general deportment gives rise to more complicated compounds.

The oxychlorides derived from antimony trioxide have been frequently examined; the results of the analyses of powder of algaroth made by different investigators varies considerably, and Sabanejeff has recently shown that these differences are probably due to the presence in the substance of antimony trichloride in varying quantities. This impurity he gets rid of by washing the oxychloride obtained by the action of a large excess of water on the trichloride with ether or carbon disulphide, in which the trichloride dissolves. In this way he obtains a compound having the constant composition $\text{Sb}_4\text{Cl}_2\text{O}_5$, or two molecules of trioxide in which one of oxygen is replaced by two of chlorine, whilst a simpler monoxychloride, SbOCl , is prepared by acting with only from 2 to 10 molecules of water on the trichloride. But this on treatment with ether or carbon disulphide loses trichloride and yields $\text{Sb}_4\text{Cl}_2\text{O}_5$; thus $5\text{SbOCl} = \text{SbCl}_3 + \text{Sb}_4\text{Cl}_2\text{O}_5$.

The results of my experiments lead me to the conclusion that the body obtained by the action of boiling water on the trichloride does not possess the composition—

but consists of 10 molecules of this substance and one of the trichloride, which latter, however, can be removed by washing with either carbon disulphide or ether. Antimony determinations in two different preparations gave—

(1) 75.45 per cent Sb. (2) 75.88 per cent Sb; corresponding chlorine determinations gave (1) 12.43 per cent Cl; (2) 12.49 per cent Cl.

Hence we have:—

	Calculated for $10\text{Sb}_4\text{Cl}_2\text{O}_5 + \text{SbCl}_3$.	Calculated for $\text{Sb}_4\text{Cl}_2\text{O}_5$.	Found.
Antimony	75.57	76.37	75.66
Chlorine	12.34	11.11	12.46
Oxygen	12.09	12.52	—

By acting upon 15 parts by weight of antimony trichloride with 1 part of trioxide in a sealed tube, Schneider (*Pogg. Ann.*, vol. cviii., p. 407) obtains a crystalline oxychloride, to which he assigns the formula $7\text{SbCl}_3\text{SbOCl}$. Repeating Schneider's experiments I obtained a pearl-grey crystalline mass melting at 72°C , the melting-point of the trichloride. When acted upon by absolute alcohol it yields powder of algaroth, $\text{Sb}_4\text{Cl}_2\text{O}_5$, and its composition appears to be even more complicated than that assigned to it by Schneider.

Antimony determinations in two specimens gave (1) 54.24 per cent Sb; (2) 54.16 per cent Sb; whilst the corresponding chlorine estimations were (1) 45.69; (2) 45.87 instead of 55.08 per cent Sb and 44.02 per cent Cl required by Schneider's formula, but agreeing with the formula $\text{Sb}_6\text{Cl}_{16}\text{O}$, which requires 54.2 per cent of antimony and 45.357 of chlorine.

The differences here found between the substances as prepared by Schneider and myself may arise from the admixture of antimony trioxide with the oxychloride in the former preparation. When the tube in which the substance has been prepared is placed in an upright position and allowed to cool, the undissolved oxide sinks to the bottom of the tube, but on still further cooling when the contents of the tube are about to solidify, the oxide rises from the bottom and mixes with the oxychloride. To obtain the substance perfectly free from undissolved oxide, the contents of the tube are gently heated, and when the finely divided oxide is deposited, the clear liquid oxychloride is drawn off with a pipette.

TESTS FOR NITROUS ACID.

By THOMAS M. CHATARD.

DURING the course of some work on the nitrites of nickel and cobalt, it was necessary to have an easy and accurate test for nitrous acid. I therefore reviewed all the tests given for that acid, comparing their relative degrees of delicacy, with the following results:—For testing, a very dilute solution of Fischer's salt—

which contained 1-200,000th part by weight of nitrous acid, was employed.

Schönbein's* test with a weak solution of indigo decolourised by potassic sulphide failed to give accurate results. Besides there are many substances which would have the same action upon the decolourised indigo as the nitrous acid.

C. D. Braun's† test with cobaltous chloride and potassic cyanide gave no reaction with so dilute a solution, even when several cubic centimetres were taken, the reaction only appearing when a comparatively strong solution of the nitrite was used.

Hadow's‡ reaction in which a nitrite when heated with

* *Jahresberichte*, 1864, 699.

† *Ibid.*, 1865, 702.

‡ *Journ. Chem. Soc.*, vol. iv., p. 341.

prussic acid, which is detected by an alkaline sulphide, gave good results only when the nitrous acid was present in larger quantities, not being delicate enough to give a reaction with the standard solution of nitrite which I employed.

A modification of this test suggested itself, in which the nitroprussic acid is thus produced. To the solution suspected of containing the acid, potassic ferrocyanide and acetic acid are added, and the whole boiled. The solution is allowed to cool, and ammoniac sulphide added. If nitrous acid was originally present, the characteristic blue reaction will appear. 10 c.c. of the test solution gave the reaction, but it failed with a smaller quantity.

The problem was finally solved by another reaction, namely, the production of phenol from aniline by means of nitrous acid. Evaporate the test liquid nearly to dryness, then rub it with a few drops of a strong solution of sulphate of aniline. If nitrous acid is present, the odour of phenol will immediately result. This test is remarkably delicate, 1 c.c. of the test solution giving a perfectly distinct reaction. Nor can nitrous be confounded with nitric acid, as this last produces no phenol, but merely a yellow colour, which of itself, as is well known, is of value as a test for that acid.—*American Journal of Science*.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 2, 1871.

Professor FRANKLAND, F.R.S., President, in the Chair.

THE minutes of the last meeting having been read and confirmed, the Secretary proceeded to read the list of donations, amongst which were two volumes of manuscript lectures of the celebrated Dr. Black's.

The names of the following gentlemen were read for the first time:—Charles Thomas, Benjamin Tanner, Hugh Paterson, Frederick Hicks, George Joseph Warner, Samuel William Moore, William John Wilson, William Gray, Robert Irvine, Reginald C. Woodcock, and Donald Munroe.

For the third time—R. Gerstl, Esq., who was balloted for and duly elected.

THE SECRETARY then read a paper on "*A Process for the Estimation of Fluorine*," by ARCHIBALD LIVERSIDGE, A.R.S.M., Scholar of Christ's College, Cambridge. The method employed consists in decomposing the fluoride by concentrated sulphuric acid in the presence of silica, and passing the silicic fluoride formed into solution of ammonia, the amount of silica carried over being then estimated, and the fluorine calculated therefrom. The powdered mineral is introduced into a platinum retort, similar to that described by Professor Maskelyne for the estimation of silica, together with the requisite amount of sulphuric acid and finely divided silica. It is now heated first in a water-bath and afterwards at 160° C., the gaseous silica fluoride thus formed being decomposed by passing it through a solution of ammonia, the last traces of the gas being carried over by drawing a current of air through the apparatus. The ammonia solution is gently evaporated in a platinum dish until the gelatinous silica passes entirely into solution, and it can then be precipitated as silico-fluoride of potassium by the addition of potassium chloride and alcohol. The difference between two determinations of fluorine in the same specimen seldom exceeded 0.05 per cent.

THE PRESIDENT said that the thanks of the Society were due to the author for his method, as there was considerable difficulty in accurately determining the fluorine in a mineral when it was present in small quantity; but he should like to have seen the results obtained by the analysis of a fluoride of known composition, in order to be certain that there was not some constant error introduced affecting the determinations.

Dr. WILLIAMSON observed that as the mineral was only reduced to an impalpable powder, and not fused with an alkaline carbonate previous to being submitted to the action of sulphuric acid and silica, it was likely, in minerals containing but a small percentage of fluorine, that the interior of the particles might escape decomposition and thus some of the fluoride remain undecomposed in the retort. In this case the results obtained would be too low.

The next paper was on "*Anthraflavic Acid*," by W. H. PERKIN, F.R.S. He first mentioned that Dr. Schunck had succeeded in isolating anthraflavic acid, a yellow crystalline substance accompanying artificially prepared alizarine, and to which he had assigned the formula $C_{15}H_{10}O_4$, Liebermann, also, in a paper on a "*Ly-Product in the Manufacture of Alizarine*," had described a substance apparently identical with the above, the composition of which, however, he gave as $C_{14}H_8O_3$, and regarded as monoxanthraquinone. The fact that this substance is found accompanying alizarine prepared from pure anthraquinone renders it far more probable that it contains fourteen than fifteen atoms of carbon; in order, therefore, to determine the nature of this body, the author prepared some anthraflavic acid by precipitating the pure baric salt by hydrochloric acid and crystallising the resulting acid from alcohol. It formed bright yellow silky needles, which were found to be anhydrous, and on analysis gave numbers corresponding to the formula $C_{14}H_8O_4$. Baric anthraflavate was prepared from the commercial alizarine by boiling it with baryta water, and precipitating the acid from the yellow solution by means of hydrochloric acid. The crude acid was then purified by washing it with alcohol and treating the product with dilute caustic soda, which leaves certain impurities undissolved. On adding baric chloride to the boiling solution and filtering, the baric anthraflavate is deposited in reddish-brown needles, which may be rendered pure by three or four re-crystallisations from water. The freshly crystallised salt was found to have the composition $2(C_{14}H_6BaO_4) \cdot 3H_2O + 10aq$; dried *in vacuo* it had the formula $2(C_{14}H_6BaO_4) \cdot 3H_2O$, and at 150°, $2(C_{14}H_6BaO_4) \cdot H_2O$, the last H_2O not being driven off even at 180°. It appears, therefore, that anthraflavic acid is an isomer of alizarine, and the author finds that it accompanies the latter in variable proportion, according to the method of experimenting. Another secondary product also accompanies artificial alizarine, and like it has dyeing properties; this the author is at present investigating.

THE PRESIDENT remarked that the isomerism of anthraflavic acid and alizarine was very interesting, indicating, as it did, the probability of there being other isomers, some of which might be found to have valuable dyeing properties like alizarine itself. As the author had not obtained any salt free from water, there was still some doubt as to whether it was a dibasic acid or not; but if it proved to be so, it would contain two atoms of oxyal, COHO, leaving the residue $C_{12}H_6$, a constituent of alizarine, which undergoes the isomeric modifications. It would, therefore, be highly desirable to settle this point by preparing, if possible, some salt free from water.

Dr. ARMSTRONG said that, as he understood that Dr. Schunck had obtained anthracene by distilling the anthraflavic acid with zinc powder, it would tend to show that the nucleus contained C_{14} and not C_{12} .

Dr. MULLER suggested treating the anthraflavic acid with benzoyl chloride, as in the case of chrysophanic potassic ferrocyanide and mercuric chloride forms nitro-

acid he had obtained anhydrous substances which were well adapted for the determination of the atomic weight.

The Secretary then read a paper "*On the Distillation of Wood*," by Mr. WATSON SMITH. The wood preferred for distillation is oak; oak crop wood and old oak timber being the kinds generally employed. The operation lasts about eleven hours, and is known to be finished when the exit pipes from the retorts become cool. The author finds that the escaping gas burns with greater luminosity just before the completion of the distillation, and that the amount of acetic acid contained in the crude wood acid which comes over gradually increases. 1000 parts of old oak timber yielded 327 of charcoal, 509 of wood acid of sp. gr. 1.025 to 1.027, and 55 of tar. The amount of wood-spirit present in the crude wood acid varies considerably, as in one instance it was found to be in the proportion of 88 gallons of sp. gr. 862 to 1000 cwts. of wood, and in another instance only 561 gallons of sp. gr. 883; some of the spirit is retained by the wood tar, which, on the average, contains about 3 per cent. of it. The crude wood acid, after being neutralised with lime, and the wood-spirit separated by distillation, may be evaporated to dryness, when it constitutes "black acetate of lime." If instead of evaporating this liquor quickly to dryness, it be boiled down, taking care to remove the tarry matters, &c., as they form, a pellicle of calcium acetate begins to form on the surface after a time; this is skimmed off as fast as it forms, drained from the mother-liquor, and dried, when it is known as "grey acetate," a purer variety than the "black acetate."

The Society then adjourned until Thursday, the 16th of November.

CORRESPONDENCE.

ELEMENTS, COMPOUNDS, AND MIXTURES.

To the Editor of the Chemical News.

SIR,—In reference to Mr. W. H. Wood's letter (CHEMICAL NEWS, vol. xxiv., p. 204), I wish to point out how the "indefiniteness" he finds in chemical teaching arises from the circumstance of a word having more than one meaning. Concerning the facts themselves there is no doubt, and the elementary treatises all properly begin by stating the indisputable truth that everybody belongs to one of two classes. For either it is a body out of which it is impossible to get any other kind of matter than itself, or it is a body out of which two or more distinct kinds of matter may be obtained. Most writers use the term "compound" to designate the latter class, and when we keep in view the ground or basis of the division, we see that all mixtures must be comprehended in this class. The object of the division is to mark off from all other bodies such as are simple or elementary, and if the terms simple and not simple, or simple and complex, had been used to designate the classes there would have been no ambiguity. The word "compound," however, in its ordinary sense, expresses that which is opposed to simple and single, and is, therefore, quite appropriately employed to denote such bodies as are not elements. Thus, Dr. W. A. Miller instances earth, air, and water, as compound bodies, in a paragraph headed "Chemical Distinction of Bodies into Elements and Compounds" (Miller's "Elements of Chemistry," part 1, p. 1).

But there is another special technical sense in which the word "compound" is most used in chemistry, namely, to denote the result of that intimate union of elements which takes place according to the laws of chemical combination. In this sense the term may be opposed to "mixture." I will quote a sentence from the first page

of Fownes's "Manual," where the word is obviously used first in one sense and then in the other.

"Nearly all the objects presented by the visible world are of a compound nature, being chemical compounds or variously disposed mixtures of chemical compounds."

Most teachers would shrink from formally dividing bodies into elements, compounds, and mixtures at the very outset of the subject, because while such a classification would be unnecessary for their immediate purpose, it would embarrass the student by making a distinction which, at the commencement, he would not be in a position to appreciate. Naquet, however, in his "Principes de Chemie," after ranking all bodies under two classes, simple and compound, subdivides the latter into combinations and mixtures, and then states the law of definite proportions and other characters which distinguish the sub-classes.

It occurs to me that this word "combination" is better fitted to express the result of chemical union than the word "compound." The relegation of this last to the ordinary sense, and the employment of the former in the place of the technical sense, would also prevent ambiguity.—I am, &c.,

R. ROUTLEDGE, B.Sc.

Bowdon, Cheshire,
Oct. 28, 1871.

ELEMENTS, COMPOUNDS, AND MIXTURES.

To the Editor of the Chemical News.

SIR,—I would suggest that the difficulty of which Mr. W. H. Wood complains may be removed somewhat in this way.

Matter is divisible into two classes, *elements* and *composite bodies*.

An element is not resolvable into two or more different kinds of matter, a composite body is separable into two or more different substances.

Composite bodies may themselves be classified under two heads, *compounds* and *mixtures*.

A compound is a body composed of two or more elements, united in a constant proportion by weight, and its properties are not the sum or mean of those of its constituents. In a mixture, however, the constituents are not united in a constant proportion by weight, and the properties of a mixture are the sum or average of those of its components.

Mixtures may be subdivided into mixtures of the first, second, and third degrees; those of the first degree consisting of elements only, as purified air; those of the second of an element or elements, and a compound or compounds, as ordinary air; those of the third, of compounds only, as solution of nitre.

This classification may be thus summarised:—

Matter.	Elements. Composite bodies.	Compounds.	
			Mixtures. 1st degree. 2nd " 3rd "

I am, &c.,

JOHN E. WRIGHT.

23, Regent Terrace, Penzance,
Oct. 28, 1871.

VAPOUR DENSITIES.

To the Editor of the Chemical News.

SIR,—I shall be glad if you can spare me space to call attention to an error in the teaching of nearly all our text-books on the subject of vapour-density determinations. If we take Roscoe's "Lessons on Chemistry," for

example, we are told that in using Dumas's method we must observe the temperature and pressure of the air in the balance-case when the glass globe is weighed full of air, but the necessity of observing these points when the globe is weighed full of vapour is not mentioned. Then, in the example given, in order to obtain the weight of the vacuum globe, the weight of air contained in the globe is deducted from the weight of the globe in air, and the weight so found is subtracted from the weight of the globe and vapour, in order to find the weight of the vapour which fills the globe.

Now, it is clear that unless we wish to go to an extreme degree of exactitude (Roscoe does not take account of the expansion of the glass) we need not observe the temperature and pressure at the first weighing, but must observe them at the second.

The observed weight of the globe full of air with the point unsealed is really the absolute weight *in vacuo* of the empty globe, minus the weight of air displaced by the glass of the globe, which is, of course, extremely small, so that this weight may be taken without sensible error as the true weight of the empty globe. Then to find the weight *in vacuo* of the globe and vapour, we must add to the observed weight the weight of air displaced at this second weighing, which may easily be considerably different from that displaced at the first weighing.

Professor Thorpe in his "Chemical Problems" follows precisely the same method as Professor Roscoe. The calculation is given correctly in the French edition of Ganot's "Physics" incorrectly in the English edition, and the error is repeated in Fownes's "Manual of Chemistry," in Pouillet-Müller's "Lehrbuch der Physik," in Kekulé's "Lehrbuch der Organischen Chemie," and (with the addition of a misprint) both in the French and English editions of Deschanel's "Traité de Physique." The same mistake appears even in Watts's "Dictionary of Chemistry," the formula in which seems to be taken from Regnault's "Cours de Chimie." Regnault also directs to observe the barometer and thermometer at the first weighing, but takes care to say that, in case the pressure and temperature alter before the second weighing, it will be necessary to introduce a correction. It is clearly better to observe the temperature and pressure at the second weighing, and if then there is any difference between these conditions at the two weighings the correction to be introduced will be much less.

The calculation is given correctly in Cooke's "Chemical Physics."

Of course no chemist in the habit of making vapour-density determinations is likely to fall into such an error, but it is extremely undesirable that in books designed for teaching a necessarily complicated subject should be rendered more difficult by the use of roundabout or erroneous methods.—I am, &c.,

W. MARSHALL WATTS.

MISCELLANEOUS.

University of London.—The following are lists of the candidates who have passed the recent B.Sc. examinations:—*Pass Examination*.—First Division. Thomas Oliver Harding, B.A., Trinity College, Cambridge; Robert Moses Lewis, B.A., Downing College, Cambridge; Thomas Hutchinson Waller, B.A., Private study. Second Division. George Thomas Betany, Caius College, Cambridge; John Cameron Graham, University College and private study; Marcus Manuel Hartog, University College, London, and Trinity, Cambridge; John Landor Lowe, King's College; William Thomas Rowden, Royal School of Mines; William Whitchurch Taunton, University College; William Thorp, private study; George Mathews Whipple, private study.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Annalen der Physik und Chemie, von Poggendorff, No. 7, 1871.

This number contains the following original papers and essays relating to chemistry and collateral sciences:—

Expansion of a Drop of Liquid on the Surface of another Liquid.—Dr. C. Marangoni.

Thermo-Chemical Researches.—J. Thomsen.—The continuation of a very lengthy essay on this subject. This portion contains the following sections:—On the quantity of heat evolved by the neutralisation of bases; lithia, soda, oxide of thallium, baryta, strontia, lime, and ammonia; magnesia, protoxides of iron, manganese, oxides of nickel, cadmium, zinc, and copper. To be continued.

Description of a Pressure Gauge for Measuring High Pressure of Gases.—V. Regnault.—Illustrated with engravings.

Researches on the Electro-Motive Force Evolved by the Contact of Different Metals, and on the Effect which Heat has thereon.—E. Edlund.—This lengthy essay is illustrated by engravings.

Refraction and Dispersion of Selenium.—J. L. Sirks.—An algebraico-optical essay.

Colouration Exhibited by Turbid Substances, and on the So-Called Coloured Photography.—C. Schultz-Sellack.

The Crystalline Form of Scheelite.—Dr. M. Bauer.—A strictly crystallographical paper. Scheelite is tungstate of lime.

Isomorphism of the Triclinic System of Crystals.—G. Tschermak.

Preparation of Pure Chromic Acid.—E. Zettnow.—After referring at length to the experiments on this subject made by Kuhlmann, Fritzsche, Warrington, and Traube, the author describes a series of experiments made with the view to ascertain the best method to prepare chromic acid in the pure state, of which the following is an outline:—For 300 parts of the commercial bichromate, 500 c.c. of water and 420 c.c. of strong sulphuric acid are taken; when, after about ten to twelve hours, the bisulphate of potassa has crystallised out, the liquor is decanted, and the crystalline mass washed with about 12 c.c. of water. The solution of chromic acid having been heated to 90°, there are added to it 150 c.c. of strong sulphuric acid, and next just as much water as is sufficient to dissolve the chromic acid which has been precipitated in the flocculent state. The solution is then evaporated until a crystalline film appears on the surface of the liquid, which is then set aside to cool until, after some 10 to 12 hours, a first crop of crystals has separated; by a further evaporation of the mother-liquor more crops (two to three) of crystals may be obtained. Since the crystals of the chromic acid are very small, it is best to decant the liquid by filtration through a cone of platinum foil perforated with many small holes, in order to free the chromic acid completely from adhering sulphuric acid. The author washes the crystals with nitric acid, sp. gr. = 1.46, which acid ought to be pure. It dissolves hardly any chromic acid, but eliminates the sulphuric acid completely.

Specific Gravity of Pure Chromic Acid and of some of its Solutions.—E. Zettnow.—The author employs benzene for the purpose of taking the sp. gr. of the acid here alluded to; the average sp. gr. of crystallised chromic acid is 2.78, while that of the fused acid is 2.802.

Preparation of Crystallised Chromium.—E. Zettnow.—To 200 parts of bichromate of potassa are added 300 c.c. of rough hydrochloric acid, 150 c.c. of water, and 80 c.c. of alcohol at 80 per cent. To this fluid mixture, which becomes spontaneously very hot, are added 180 parts of chloride of potassium, and the whole evaporated to dryness, next gently ignited in a crucible so as to drive off all water, and the dry mass after having been broken up into small lumps is divided into four equal parts, and to each of these is added 50 parts of small chips of zinc-foil. This mixture keeps perfectly well in dry and stoppered bottles, but deliquesces by exposure to air. Each portion of this mixture is gradually placed in a bright red-hot crucible, and after the reduction of the chromium has taken place and the mass is cooled, it is first boiled along with water, and then treated with very pure and very dilute nitric acid, which dissolves the zinc and leaves the chromium in crystalline form. The author intends to publish further details on this metal in a future paper.

Apparatus for Exhibiting Momentum (Vis Inertiæ).—A. Kurz.—Accompanied by engravings.

Erythroscopie and Melanoscopie.—E. Lommel.—An optical treatise.

No. 8, 1871.

This number contains the following original papers and memoirs:—

Continuation and End of Essay on Thermo-Chemical Researches.—J. Thomsen.

Researches on the Electro-Motive Force Evolved by the Contact of Different Metals and on the Effect which Heat has thereon.—E. Edlund.—Continuation and end of this very exhaustive essay.

Behaviour of Chlorophyll towards Light.—Dr. E. Lommel.

Action of Light upon Chlorophyll.—Dr. E. Gerland.—The contents of these essays are not suited for useful abstraction.

Water and Common Salt Contained (Occluded) in Rocks and Minerals.—Dr. F. Pfaff.—This paper, illustrated by several engravings, treats on the method of determining the quantity of water mechanically occluded between the pores and particles of rocks and minerals, while it appears that in many instances this water contains common salt also. The main result of the author's researches are:—All granitic rocks contain water mechanically occluded between the component crystals; the quantity of this water varies considerably, viz., from 0.11 to 1.8 per cent; the rocks alluded to and also the sedimentary rocks contain, in addition to water, chloride of sodium occluded; no water was found in any kind of lava, obsidian, and basalt.

On Sulphur Crystallites.—H. Vogelsang.—This paper is a reply to some critical observations made by Dr. E. Weiss on an essay published by the author some time since on crystallites.

Limits of the Sensitiveness of the Eye for Spectrum Colours.—S. Lamansky.—An algebraico-optical essay; an observation also relating to the following essay:—

The Spherical Electro-Dynamometer.—O. Frölich.

Spectra Exhibited by Lightning.—Dr. H. Vogel.—The account of thunder observations made on the lightning during a severe thunderstorm, which lasted for several hours, on September 2 last.

On Coloured Gelatine as Suitable Objects for the Spectroscope.—E. Lommel.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 8, 1871.

This number contains the following papers relating to chemistry:—

New Mode of Formation of Diethyl Sulphate.—E. Dubois.—After referring to researches made by Dr. Odling and M. Baumstark, the author describes some of his experiments on the action of chloride of sulphur upon alcohol. The reaction is very violent, and the result is the formation of a body, $(C_2H_5)_2SO_4$, according to the following formula:—

Conversion of Citric Acid into Tricarballic Acid.—E. Dubois.—The author begins this essay by observing that on examination of the three following formulae:—

Tricarballic acid. Aconitic acid. Citric acid.

it will be observed that there exist between these acids the same relation as exists between the following acids:—

Succinic acid. Fumaric acid. Malic acid.

The author next states that, by the aid of the action of iodhydric acid (at 50° B.) upon citric acid, continued for thirty hours, he has succeeded in converting the citric acid into tricarballic acid, fully identical in every respect with the properties of that body and its salts as described by Dr. Maxwell Simpson.

The American Journal of Science and Arts, October, 1871.

This number contains, in addition to the lengthy papers and essays on geology, palaeontology, natural history, and astronomy, the following paper which, to some extent, bears on chemistry:—

The Paragenesis and Derivation of Copper and its Associates on Lake Superior.—R. Pumphrey.—The continuation of a lengthy essay on this subject, setting forth the mode of formation of the minerals met with along with the metallic copper deposit alluded to. This paper is to be continued.

Journal für Gasbeleuchtung und Wasserversorgung, No. 18, 1871.

The original matter contained in this number only refers to gas-and water-works' engineering and management.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, August, 1871.

The original papers relating to chemistry and published in this number are:—

Second Paper on the Native Compounds of Tantalum and Niobium.—Dr. Rammelsberg.—The continuation of an exhaustive mineralogical essay on this subject, to which are added a very large number of chemical analyses of the minerals tyrotrantalite, Fergusonite, bragite, tyrite, euxenite, and others herein treated of.

Methylation of the Phenyl Group in Aniline.—Dr. A. W. Hofmann.—This lengthy essay, elucidated by a series of complex

formulae, contains the following sections:—Introduction; dimethyl-aniline; dimethyl-toluidine; dimethyl-xylylene; dimethyl-cumidine; dimethyl-cymidine.

Journal für Praktische Chemie, Nos. 15 and 16 (double number), 1871.

Nos. 13 and 14 of this periodical will be abstracted as soon as we obtain them. This number contains the following original papers and memoirs:—

Contribution to our Knowledge of some of the Chromium Compounds.—L. J. Heintze.—This essay treats at great length on the author's results of experiments, made with the view of preparing amido-chromium compounds. We regret that the great length of this succinctly-written memoir does not admit of any further account than the quotation of the headings of the different sections:—Introduction; action of ammonia upon potassium chloro-chromate; action of ammonia upon chromic acid chloride.

Mineralogical Notice.—A. Frenzel.—This paper treats on Pucherite, a mineral named from the locality, Pucher-Richtschacht, Saxony, where it occurs. This substance has a sp. gr. = 5.91, and is a compound of oxide of bismuth and vanadic acid; formula, $Bi_2O_3.V_2O_5$. In 100 parts:—Oxide of bismuth, 71.49; vanadic acid, 28.51. The main portion of the contents of this paper are strictly mineralogical.

Action of Light upon Chlorine and Bromine.—E. Budde.—This paper contains a preliminary account of a series of experiments, made with the view of inquiring more accurately into the phenomena of combustion and catalysis. The following points deserve notice:—Light decomposes the molecules of chlorine; highly refrangible light has upon chlorine an effect not quite known by being converted into heat, giving rise to the expansion of this gas; the division of the spectrum, adopted by Sebeck and Melloni, into a heating and non-heating chemically active portion, is not correct, because there exist bodies which are far more heated by the violet than by the red-coloured rays; in fact, the division alluded to only applies to surfaces covered with lamp-black; bromine behaves as chlorine does.

Table Exhibiting the Quantity of Neutral Molybdate of Soda in Aqueous Solution.—B. Franz.

The Methods (Moden) of Modern Chemistry.—Dr. H. Kolbe.—Notwithstanding the high scientific value of this lengthy and very carefully written essay, its contents are not suited for useful abstraction, an observation also applying to the following paper:—

On some Electro-Capillary (Chemosmotic, Chemosmotische) Phenomena.—O. Loew.

Theoretical Observations on the Colours Exhibited by Bodies.—W. Stein.—This essay contains some very important facts bearing upon a difficult subject, but does not admit of any further quotation.

Estimation of Sulphur in Ultramarine.—W. Stein.—The main gist of this paper is that, instead of arsenious acid, sulphate of copper, but not chloride of copper, may be advantageously used.

Essay on the Spectrum of Calcium.—R. Blochmann.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, October 26, 1871.

This number contains the following original papers:—

Continuation of the Memoir on the Dissociation of Bodies.—C. Mène.

New Method of Preparing Pulp for Paper-Making Purposes from Wood.—M. Cattell.—The detailed description of a series of mechanical and chemical operations by which paper-pulp may be obtained from wood.

Bleaching Cotton, Hemp, Flax, Jute, and other Vegetable Fibres, by the Aid of Permanganates.—Tessie du Motay.—The description of a certainly very effective, but also rather complicated, process of bleaching, requiring not only permanganates, but, after its application, sulphurous acid, and then again alkalis.

Bibliography.—Under this title we call attention to the following works:—"Exposé d'un Système à Vapeur Economique ou à Détente très Prolongée," par M. Autier; a volume containing engravings. The contents of this work are highly spoken of, and especially worth notice on account of the greatly lessened consumption of fuel by the adoption of the author's system now in practice in several parts of France. "De la Notation Atomique et de sa Comparaison avec la Notation en Equivalents," par le Dr. Micé, chez Baillière, Paris. The contents of this work are, according to the short review here given, well worthy the attention of all scientific chemists.

November 2, 1871.

This number contains the following original essays and papers:—

Continuation of the Studies on the Chemical Dissociation of Bodies.—C. Mène.

Chemical Researches on Food Substances.—C. Mène.—The first portion of an elaborate chemico-physiological memoir, treating on digestion as an introduction.

New Apparatus for Heating Wines.—C. Tellier.—This paper, illustrated by woodcuts, describes a contrivance for ameliorating and maturing wines by the aid of heat.

Varying Quantity of Alcohol met with in the Wines Produced in Different Countries.—Drs. Blaukenhorn and Roessler.—A tabulated form exhibiting the names of different wine-growing countries

their mean annual temperature, the sp. gr. of the wines, and quantity of alcohol by volume per cen. contained therein.

Bibliography.—Under this heading are published short reviews of the two following recently published books:—"Traité Complet de la Tourbe," par M. E. Boac. From what is here published on this work it appears to deserve the notice of all who are interested in the question of the best and most advantageous modes of utilizing peat. "Essai sur les Gravures Chimiques en Relief," par M. Motterot. This work contains all, and the best, information on the subject of substituting for xylography a more rapid and yet equally satisfactory method of producing engravings which can be printed along with ordinary type.

Gazzetta Chimica Italiana, No. 7, 1871.

This number contains the following original papers and memoirs:—

Action of Perchloride of Phosphorus upon Bichloride of Aldehyde.—E. Paterno and G. Pisati.—The main results of this excellent essay may be resumed as follows:—Pure bichloride of aldehyde behaves with perchloride of phosphorus in the same way as do all the aldehydes, giving rise to the formation of a compound of the formula $C_2H_2Cl_2$; while, by the reaction which takes place, there is always formed a small quantity of the compound $C_2H_2Cl_2O$, due to the impossibility of completely excluding hydrochloric acid.

Presence of Manganese in Blood as a Permanent Constituent of that Liquid.—G. Campani.—This subject has been taken up by the author in consequence of a paper published in another scientific Italian periodical, wherein Dr. Pollacci asserts that manganese is an integral constituent of blood. It appears from the author's experiments, made with blood of oxen, that the globules as well as the serum contain, along with iron, weighable quantities of manganese.

Spectroscopical Characters of an Ammoniacal Solution of Carmine, of Cochineal, and of other substances.—G. Campani.

Urea a Product of the Spontaneous Decomposition of an Aqueous Solution of Hydrocyanic Acid.—G. Campani.—By the slow decomposition of the acid alluded to, there is formed, in addition to a brownish coloured amorphous substance (paracyanogen), a crystalline compound, which, on being tested with nitrate of mercury and other reagents, was found to be urea.

Contribution to our Knowledge on Sulphide of Carbon.—F. Seetini.—This paper is as yet only an abstract of an essay on this subject, but from what is here published we learn that sulphide of carbon is not quite insoluble in water, for if the sulphide is agitated along with pure water for several hours a perfect aqueous solution of the sulphide of carbon is obtained, which contains by weight 1 part in 1000 of water. When a mixture of water, of hydrate of lime, and of sulphide of carbon, is exposed to the action of the sun's rays, there is formed sulphocarbonate of lime, a reddish coloured solid substance, $3(CaH_2O)_2 + CaSC + 7H_2O$. As a very delicate test for sulphide of carbon, the author makes use of the aqueous solution of the sulphide, to which is added some solution of caustic potassa, and this mixture heated for five minutes to 50° ; when then acetate of lead is added an abundant precipitate of sulphuret of lead is formed. The author states that by this test 1-10,000th part of sulphide of carbon may be detected.

No. 8, 1871.

This number opens with a lengthy essay:—

On a Supposed New Volcano in Sicily.—O. Silvestri.—A geologico-chemical paper of importance, especially to elucidate volcanic action.

Action of Sulphur upon Olive Oil.—L. Moschini.—The main point of interest in this paper is that olive oil, in its natural state, contains in solution a yellowish coloured substance, which, when acted upon by sulphuric acid (sp. gr., 1.63) and by nitric acid (sp. gr., 1.33), gives rise to a greenish colouration, while, with caustic soda solution (sp. gr., 1.34), a bright yellowish colouration is produced. After exposure to sunlight this coloured substance is so modified that the reagents alluded to do not produce the same reactions; moreover, by the action of the sun, the olive oil is entirely altered, imparting to it many of the properties of claudine, while, if the action of the sun's rays is very prolonged, there are free acids formed, and the olive oil becomes rancid.

Pharmaceutische Zeitschrift für Russland, Nos. 12, 13, and 14, 1871.

These numbers do not contain any original papers relating to chemistry and allied sciences.

No. 15, 1871.

This number contains the following original paper:—

On Picrotoxin and some of its Derivatives.—Dr. J. Gaabe.—This exhaustive essay obtained the golden Suworow medal from the Medical Faculty of the University of Dorpat. The first part of this paper gives a detailed account of all that has been done as regards chemical research of the so-called *Cocculus indicus*, the berry of the *anamide*, or *Menispermum cocculus*, from 1730 (C. Neumann) up to the present day. The second portion of this paper records the author's experiments, divided into the following sections:—Preparation of pure picrotoxin; action of caustic potassa solution upon picrotoxin; action of sulphuric acid upon picrotoxin. From the tabulated form printed at the end of this essay we learn that the following are the main results of this research:—Picrotoxin, $C_{12}H_{14}O_8$; hydro-picrotoxin, $C_{12}H_{14}O_8$; oxy-picrotoxin, $C_{12}H_{12}O_8$; oxyhydro-picrotoxin, $C_{12}H_{12}O_7$;

dioxypicrotoxin, $C_{12}H_{12}O_7$; dioxhydro-picrotoxin, $C_{12}H_{12}O_6$; trioxypicrotoxin, $C_{12}H_{10}O_6$; trioxhydro-picrotoxin, $C_{12}H_{10}O_5$.

No. 16, 1871.

This number contains no original papers relating to chemistry.

NOTES AND QUERIES.

Lute.—(Reply to W. S.)—Loam or pipe-clay will probably answer your purpose.

Paraffin and Naphthalin.—Could any of your readers inform me of a method of testing the difference between paraffin and naphthalin? I have a lot of solid matter that comes off at a temperature of 370° to 450° F., or before all the light oil is off in the distillation of tar.—THOMAS DANKS.

Elements, Compounds, and Mixtures.—With reference to the questioned raised by Mr. W. H. Wood in your last number, permit me to quote the following from page 3 of Dr. Miller's useful little "Introduction to Inorganic Chemistry"—"Every material object with which we are acquainted is, in a chemical point of view, either an element or a compound, or else a mechanical mixture of two or more elements or compounds." This appears to meet the case of natural mixtures having, within certain limits, a definite composition.—GEORGE CHALONER, Birkbeck Institution.

Purifying Coal-Gas.—(Reply to M. H.)—The gas which is supplied from the gas-works is not, as a rule, too impure for heating purposes, but if you desire it purer, especially as you only appear to require it on the small scale, pass the gas, previous to burning it, through an alcoholic solution of caustic potassa or caustic soda, whereby you will eliminate from the gas any sulphide of carbon and sulphuretted hydrogen it might happen to contain. If, however, you make your own gas, try the processes described by the Rev. W. R. Bowditch, M.A., in his work "The Analysis and Purification of Coal-Gas," published by Messrs. Spott; London, 1867.

Gallic Acid.—Ilugo Tamn writes in a dashing, confident style, but wherefore does he notate gallic acid as $C_7H_5O_6$? ($C=6$, $O=8$)? M. Schiff regards—

Gallic acid as $C_{14}H_{10}O_{10}$
Tannic acid $C_{28}H_{18}O_{20}$
Tannin $C_{28}H_{22}O_{21}$

The formation of these bodies conform to a generic formula of production.

Gallic acid + gallic acid - $2HO$ = digallic (tannic acid).
3 Gallic acid + sugar - $6HO$ = tannin, or trigallic glucoside.

The relation of tannic acid to anthracen and many other items seem to justify the latest opinion of that distinguished chemist.—S. E. P.

MEETINGS FOR THE WEEK.

MONDAY, Nov. 13th.—London Institution, 4. Prof. Huxley, LL.D., F.R.S., on "Nervous Matter: its Structure and Properties."

THURSDAY, 16th.—London Institution, 7.30. Harry G. Seeley, F.G.S., on "The Influence of Geological Phenomena on the Social Life of the People."
Chemical, 8.

TO CORRESPONDENTS.

* Vol. XXIII. of THE CHEMICAL NEWS, containing a copious index, is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxiv. commenced on July 7th, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each, post free, may also be obtained at the Office.

ERRATA.—Vol. xxiv., p. 208, col. i., line 7 from bottom, for " $SbO_3(C_7HO_3)_2 + 3HO$ " read " $SbO_3(C_7HO_3)_2 + 3HO$." Col. ii., line 6 from top, for " $(1.) SbO_3(C_7HO_3)_2 + 3HO$ " (2.) " $SbO_3(C_7HO_3)_2 + 5HO$," read " $SbO_3(C_7HO_3)_2 + 5HO$."

C. S. E. Wood.—You will find the information you require in Crookes and Röhrig's "Metallurgy," vol. ii.

X. Y.—Hypochlorite of lime liquor is made by passing chlorine gas through a mixture of lime and water placed in cisterns; the solution possesses similar properties to dry bleaching-powder.

J. Leith.—A work treating on the subject is in the press.

VOL. XXIV. No. 625.

GALVANIC BATTERY ELEMENTS.

By W. H. COFFIN.

HAVING made a series of tests with various galvanic elements, with a view of determining experimentally their respective adaptabilities for telegraphic, signal, clock, and other work, their relative cost, constancy, and strength; I send you a brief account of the results, thinking them to be of sufficient general interest.

The following cells were prepared:—

(a). Leclanché's. Zinc, ammoniac chloride solution in water, and manganic oxide mixed in the state of coarse powder with fine crushed best gas carbon, and packed with larger pieces of carbon in porous cell around carbon block. Reduced probably to dimanganic trioxide.

(b). Similar to (a), with the substitution of plumbic peroxide for manganese, and sulphuric acid 1 to water 25 for ammonia solution.

(c). A modification of Marié-Davy's element, zinc, sulphuric acid 1 to water 25, and mercuric sulphate; securing equal electromotive force with much greater constancy.

(d). Zinc, water, and plate of carbon; the latter descending to the bottom of receptacle, and dipping into a layer of mercuric sulphate. Zinc and carbon closely approximated, no porous division.

(e). Highton's new element, zinc, ammoniac sulphate solution in water, and carbon in porous cell, packed with crushed carbon, and surmounted by a tower of cinders. Was made as closely as possible according to the inventor's description, the porous cell being selected for porosity and size, being three inches in diameter, and extending to about six inches above the surface of the solution, the upper part pierced with numerous holes.

(f). Zinc, sulphuric acid 1 to water 25, and carbon packed exactly as in (a), minus the manganese.

(g). New cell.

(h). New cell.

(i). New cell.

The elements (c), (g), (h), (i), if still satisfactory after further research and modification, will be made public.

All zincs exposed equal surfaces to solution. Porous cells, with the exception of (e) being precisely similar, and saturated for an inch from the bottom with paraffin. Chemicals, with the exception of acids, being the ordinary ones of commerce; zinc well amalgamated, ordinary best Belgian rolled, and the weight of substances at the negative pole being in each case, except (e) and (f), sufficient to neutralise the hydrogen displaced by one ounce of zinc.

Current variations were determined by a very sensitive tangent galvanometer, having a diameter-needle ratio of 20, $R=0.09$ Ohms, and reading easily by estimation to $15'$ or $20'$.

A word of explanation will be necessary respecting the electromotive forces as entered in the table. These were measured after poles were connected for two seconds by a small resistance of 0.197 Ohms. By this method I think a more correct estimate can be made of the practical value of the element, for the potential, though constantly falling on short circuit, decreases to a very remarkable extent during the first two seconds only, the fall after that interval being inconsiderable in comparison; the ratio between the force tending to produce a current, and the current that can be maintained, even on long circuit, differs to a remarkable extent between the various descriptions of cells; for example—the element (a), by connecting with a condenser of not too exten-

sive a surface, and discharging through galvanometer, indicates about 1.49 volts, whereas, if tried after two seconds current through 0.197 Ohms, indicates as in the table only about 1.137 volts., being then considerably less than some elements whose initial forces are much less than that of (a) at first.

It is quite evident that the force as estimated by first method is seldom, if ever, available in practical telegraphy, especially in charging cables of great electrostatic capacity, whereas, by the method pursued here, results are obtained that can be accepted with confidence. The electromotive force was in each case every time determined by three distinct methods, namely—that indicated above; the method of Fechner or Wiedemann of sum and difference in comparison, the galvanometer above alluded to being employed; and the other method due to Fechner, of direct comparison through high resistance, using a sine galvanometer of great delicacy, having 2000 turns of fine wire, and a resistance of about 4560 Ohms.

Zincs being weighed and poles insulated for 60 minutes, the potentials (e) were measured and inserted in col. 2 of table. After thirteen hours open they were coupled in series, each one working through resistance of $R=\Sigma r+0.197$ Ohms. for 60 minutes, the variation in current strength during that interval being as in col. 3, the signs + (inferred) and — denoting in this and all other determinations of current variation an increase or decrease in the same, respectively, unity being taken as that current producing a deflection of 45° on a certain galvanometer. 36 hours from this, with poles insulated in the interval, E was again measured and inserted in col. 4. Working in the same conditions as in col. 3 for 6 hours, the variations were as in col. 5, after which the variations with open poles in 15 minutes were entered in col. 6. Col. 7 shows the potentials one hour after last experiment. In col. 8 is the variation in 12 hours through $R=\Sigma r+379$ Ohms. Cols. 9, 10, and 11 show the variation in three consecutive intervals of 5 minutes each, through $R=0.197$ only. Col. 12 contains the variation in the next 5 minutes through $R=0$. The potentials after 2 hours' open poles were then found to be as in col. 13. Poles were insulated for eighteen days, and loss of zinc since beginning of experiments was found to be as in col. 14, in grs. The absolute resistance of each cell was undetermined, but their relative resistances were measured both before and after tests, and in cols. 15 and 16 are indicated by numbers the inverse order of their resistances—that is to say, from the most to the least conductable, before and at the termination of the experiments respectively.

The zinc of (a) was in the best condition, smooth and clean, but with a few small crystals, and a fine black pulverent non-adhesive deposit; (e) was slightly more attached, but covered with a quantity of large crystals, forming a continuous coat; (c), (g), (h), (i), were quite clean, but slightly pitted and rough on surface; (b) was quite dirty, very rough, and showing traces of much local action; (d) was very much attacked, great local action. These results, I think, afford sufficient data for valuable inference. I should select (g) where great constancy was particularly essential and final cost a consideration; the negative pole of this element being absolutely perfectly insoluble in the solution, unaffected by it for any length of time, and the cost of replacing it very small indeed. When continuous action with high electro-motive force is required, element (c) is indicated. The same on short circuit, where conductivity is and expense is not a consideration, will indicate (d). When the battery is not to be called upon for an indefinite period of time, and then only occasionally on long circuit, element (a) should be selected, especially if it is to be placed in inaccessible positions, the cost of maintenance under such circumstances being remarkably small. When, however, great economy in working is essential, and constancy not particularly necessary, the element (e) is certainly the best if it is to be rather constantly used, and on long circuit.

NOTES OF

DEMONSTRATIONS ON PHYSIOLOGICAL
CHEMISTRY AT ST. GEORGE'S HOSPITAL.

By S. W. MOORE.

III.

URIC acid (H₂C₃H₂N₄O₃). White crystalline powder, 1 part soluble in 10,000 parts water. Crystallises in rhombic tables; these are modified in the presence of colloid matters, and form lozenges, as in morbid urine. It combines with bases to form salts, as urate of ammonium, which so frequently separates from the urine on cooling, and is again dissolved by heat.

Uric acid occurs most largely in the excrement of serpents, which consists almost wholly of urate of ammonium. It is contained also in healthy urine and in the blood, traces in the sweat (Stark), &c.; in some morbid states of the system uric acid is abundant, separating from the urine in red grains, and in gout is secreted by the synovial membranes as urate of lime.

Uric acid may be readily obtained from urine by evaporating to 1/4th part of its bulk and adding HCl, when the crystals separate. In abnormal urine the simple addition of HCl is sufficient if the acid be present; to demonstrate it in gouty blood, Garrod recommends that the blood be acidulated with acetic acid, a thread placed in it and left for twelve hours, crystals then form on thread; this is conveniently done in a watch-glass.

Calculi frequently occur composed of impure uric acid, though sometimes in combination with a base.

The best method of obtaining pure uric acid is to dissolve boar excrement in KHO and add HCl, collect the precipitate and repeat the operation, when, on drying, you will have the acid pure.

Decomposition Products.

Uric acid is readily acted on by oxidising agents, and a large number of products obtained; the most important are the following:—

Alloxan (C₄H₄N₂O₅, 3H₂O). Obtained by adding dry uric acid to HNO₃, sp. gr. 1.42, keeping the vessel cool as violent effervescence ensues. When sufficient uric acid is added, alloxan separates in crystals.

It crystallises in octahedra, which become pink by exposure to light; a solution stains the skin pink, and communicates a sickly odour. Alloxan is not acid, but reddens litmus paper, and gives a purple reaction with a ferrous salt.

Alloxanic acid (H₂C₄H₂N₂O₃). Treat alloxan with BaH₂O₂ until precipitate does not dissolve, and gently heat; baric alloxanate produced. Add cautiously H₂SO₄, filter and evaporate; crystals of the acid form.

Mesoxalic acid (H₂C₃O₃). Boil baric alloxanate and baric mesoxalate precipitates; H₂SO₄ sets the acid free; it is very soluble.

Parabanic acid (H₂C₃N₂O₃). Obtained from the mother-liquor of alloxan by concentration and crystallisation.

Ammonium parabaranate on evaporation breaks up into ammonium oxalurate; H₂SO₄ sets free the acid.

Alloxantin by reducing alloxan with H₂S, &c.

Boiling solutions of alloxantin and NH₄Cl mixed in a tube, corked, and cooled, form crystals of uranil.

Murexid or purpurate of ammonium may be obtained by adding alloxan to an ammoniacal solution of uranil; thus, step by step, we descend the ladder of the series, keeping the original uric acid still in sight.

The production of murexid is the most characteristic test for uric acid. A portion of the substance is dissolved in HNO₃, the solution evaporated to dryness and ammonia added, if uric acid be present, murexid is formed; this is changed to a violet colour by adding KHO.

From what we have now seen in the changes this body may undergo, it is not improbable that in the animal economy many phases of disease are dependent on the imperfect modifications of this acid, its oxidation being arrested at too early a period or advanced beyond its proper limit.

Allantoin occurs in the allantoinic fluid of the foetal calf, and is procured by oxidising uric acid.

There are many other derivatives, but most of them are comparatively unimportant.

Cystin occurs in a rare form of calculus, and is, perhaps, strictly a pathological product; its formula is C₂H₆N₂O₂S. It contains 25.5 per cent of sulphur, and crystallises in hexagonal plates from its solution in ammonia; when heated it gives off a foetid odour.

Hippuric acid (HC₉H₈N₂O₃) is present in large quantities in the urine of herbivora; traces occur in healthy human urine. This acid is closely allied to benzoic. If a horse be kept at rest no change occurs in the hippuric acid, but when worked it changes to benzoic; when benzoic acid is taken by man it is converted to hippuric acid in the urine.

Its constitution seems to be that of glycocine with an atom of H displaced by benzoyl, HC₂H₃(C₇H₅O)NO₂. It crystallises in rhombic prisms, and may be obtained from cow's urine by acidulation with HCl, in long silky needles; it melts at 240° C., is converted into benzoic acid and benzonitrile, a red oil smelling of Tonka beans.

ON AURINE.*

By R. S. DALE, B.A., and C. SCHORLEMMER, F.R.S.

IN the July number of the *Journal of the Chemical Society* we have published a short note on "Aurine," a colouring matter discovered by Kolbe and Schmitt, in 1861, and which is now found in commerce under the name of aurine, yellow coralline, or rosolic acid. The commercial product which is obtained by heating phenol with oxalic and sulphuric acids, is a mixture of different bodies, from which we have isolated the pure colouring matter by dissolving the crude aurine in alcohol, and treating this solution with ammonia. A crystalline precipitate, a compound of aurine with ammonia, separated out, whilst the other bodies present remained in solution. The ammonia compound was washed with alcohol by means of Bunsen's filter pump, and decomposed by dilute acetic acid. The

* Read before the Manchester Literary and Philosophical Society October 31, 1871.

aurine thus obtained was further purified by repeated crystallisation from strong acetic acid. It crystallised in rhombic needles or prisms, the colour of which varies according to the concentration of the acid, and as it appears also, according to the purity of the substance. We have obtained it in needles having the colour of chromic acid, and a brilliant diamond lustre, or in darker red crystals of varying shades, with a steel-blue, greenish-blue, or splendid beetle-green reflection. We have analysed these different specimens, partly dried at 100° and partly at higher temperatures, and although samples of the same preparation gave very agreeing results, those of different preparations varied very much in their composition. The reason of this is, that aurine retains most obstinately water and acetic acid, a fact which has also been observed by Fresenius,* who has lately published a note on the same subject.

From concentrated hydrochloric acid aurine crystallises in fine hair-like red needles, which, dried at 110°, contain a large quantity of hydrochloric acid. We tried to obtain the pure compound by precipitating a dilute alkaline with dilute hydrochloric acid, and washing the precipitate by Bunsen's filter pump, but also this product contains hydrochloric acid, which was only given off above 110°.

By spontaneous evaporation of an alcoholic solution, aurine is obtained in dull red crystals, with a green metallic lustre. Dried at 110° this body contains no alcohol, but still retains a large quantity of water, which only escapes between 140° to 180°, the crystals not changing their appearance at all, and they may be heated up to 200° without any further alteration, which fact does not agree with Fresenius's observation, that aurine crystallised from alcohol or acetic acid melts at 156°. The analysis of this body, dried at 200°, which we believe to be pure aurine, gave numbers closely agreeing with the formula $C_{20}H_{14}O_3$, and the mode of its formation may, if this formula is correct, be expressed by the equation

The substance dried at 170° lost at 180° 5.4 per cent of water corresponding to the formula $C_{20}H_{14}O_3 + H_2O$.† Caro and Wanklyn obtained by the action of nitrous acid on rosaniline a body, which they believe to be identical with aurine, and to which they assign, from the mode of formation, the composition $C_{20}H_{16}O_{3\frac{1}{2}}$, differing from our formula only by two atoms of hydrogen.

Nascent hydrogen converts aurine into colourless leuco-aurine, $C_{20}H_{18}O_3$. This reduction may be effected by heating it in an alkaline solution with zinc dust, but at the same time a dark resinous body is formed, from which the leuco-aurine cannot be easily freed. Better results are obtained by acting with zinc dust on a solution of aurine in strong acetic acid. Leuco-aurine crystallises from acetic acid or alcohol in compact colourless prisms.

A body resembling leuco-aurine is contained in crude aurine; we have not as yet obtained it in a pure state. It differs from leuco-aurine, however, by yielding a purple solution on adding potassium ferricyanide to its alkaline solution, whilst leuco-aurine under the same conditions is oxidised to aurine, which dissolves in alkalis with a magenta red colour.

By passing sulphur dioxide into a hot alcoholic solution of aurine, brick-red crystals separate, being a compound of aurine with sulphur dioxide. They do not smell of sulphur dioxide, undergo no change when exposed to the air, and are only decomposed at a temperature above 100°, when they split up into sulphur dioxide and aurine.

On mixing an alcoholic solution of aurine with a solution of a bisulphide of the alkaline metals, the liquid becomes

colourless, a compound of aurine with the bisulphide being formed, which by spontaneous evaporation of the solution, is obtained in splendid colourless needles. These compounds are decomposed by acids as well as alkalis. We have not as yet analysed these different compounds, but intend to do so, hoping thus to find the correct formula for this remarkable compound.

By heating aurine with alcoholic ammonia in closed vessels to 110°, the so-called red coralline is obtained, a body which has great resemblance to the yellow aurine, but dyes a redder shade. This compound we have also obtained in fine crystals.

ON THE
SEPARATION OF THE OXIDE OF IRON FROM
OXIDE OF URANIUM,
AND THE
ESTIMATION OF PHOSPHORIC ACID BY
MEANS OF URANIUM.

By H. RHEINECK.

ACCORDING to Arendt and Knop (see the fourth German edition of Fresenius's "Quantitative Analysis," p. 421), a precipitate of oxide of iron containing uranium is obtained when a mixed solution of the acetates of these two oxides is boiled. In order to separate, in this manner, the iron from the uranium, the nitric acid solution of the two oxides was first as nearly as possible neutralised with carbonate of soda, next converted into acetates by the addition of acetate of soda, and thereupon diluted with water to fifty times the weight of the oxides present. Since I observed that when a solution of acetate of uranium is boiled over an open fire there is a great chance that oxide of uranium is deposited on the sides of the vessel wherein the liquid is contained, I heat the vessel on a water-bath. A small quantity of the precipitate thus formed, having been tested directly after the precipitate was formed, was found to be free from uranium; but the bulk of the precipitate having been left standing for a length of time, without having been first thoroughly well washed, exhibited a crystalline admixture, which could only be removed by being heated with a large quantity of water, care being taken to heat on the water-bath, and the oxide of iron was then found to be quite free from uranium. The small crystals alluded to, having been separated from oxide of iron adhering thereto, were found to possess the peculiar colour of salts of oxide of uranium and a tetrahedral shape. I considered it of some interest to make a further investigation of these crystals.

When to any salt of oxide of uranium in aqueous solution acetate of soda is added, the result is, that either at once, or in more dilute solutions after some time, a crystalline compound is precipitated. This precipitate exhibits the following properties:—Shining, hard, small crystals, chiefly octahedra. This body is not acted upon by either air or light, not even in aqueous solution under the direct action of sunlight. 1 part of this substance requires 25 parts of water at the ordinary temperature for solution, and the substance may be heated to 130° without undergoing any change. When heated in contact with air to moderate red heat the material burns off, the acetic acid being destroyed, and there is left yellow oxide, of which, by two different experiments, I obtained 68.68 and 67.21 per cent. By heating with sulphuric acid in excess, and continuing the heating to incipient red heat, so as to drive off all the excess of sulphuric, and also the acetic acid completely, it yielded a residue of 93.82 per cent. Phosphate of soda, having been first acidified with acetic acid, yielded a precipitate which, after ignition, amounted to 78.15 per cent. Since there is no water of crystallisation, this loss by ignition represents acetic acid ($C_4H_3O_3$),

* Journ. f. Prakt. Chem., No 70, 1871.

† Fresenius analysed aurine which was crystallised from alcohol and dried at 100°. His numbers agree exactly with the formula $C_{20}H_{14}O_3 + 2\frac{1}{2}H_2O$.

‡ Proc. Roy. Soc., xv., 210.

and gives, when compared with the phosphoric acid precipitate, a clue to the composition of the crystalline substance. The quotients $\frac{100-68.68}{C_4H_2O_8}$ and $\frac{100-67.21}{C_4H_2O_8} = \frac{31.32}{59}$, and $\frac{32.70}{59} = 0.614$ and 0.643 stand to the quotients $\frac{78.15}{(U_2O_5)PO_4} = 0.2176$, about in the relation as three to one;

therefore there are upon 3 equivalents of acetic acid 2 equivalents of oxide of uranium, the rest being soda. The formula $(U_2O_5)_2Na_3C_4H_3O_3 = 472$, when is taken $U = 60$, requires 67.59 per cent of residue after ignition, also 94.70 per cent of sulphate of uranium, $(U_2O_5)_2Na_3SO_4$, and lastly 76.05 per cent of pyrophosphate of oxide of uranium. Consequently the salt hereinbefore alluded to is the same as that which Wertheim* described as being obtained by mixing acetic acid combinations of uranium and soda in aqueous solution. In order to apply this salt to the volumetrical estimation of phosphoric acid, I proceed just in the same manner as has been described by Stohmann†; but the preparation of the uranium liquid can be more simply done, while, moreover, a previous test-titration by means of phosphate of soda can be dispensed with. The solution of the salt (to be weighed in the state either of very small crystals or ground up) may be made at the ordinary temperature. I prefer to take of

the double salt $\frac{47.2}{2}$ gm. to 1 litre of water, so that it is a normal solution at $\frac{1}{10}$ th; that is to say, 1 c.c. indicates 0.00005 gm.-equivalent, or 0.00355 gm. of PO_5 . Such a solution does not throw down crystals (viz., of the double salt), and the solution might be even more diluted. While experimenting, I purposely employed upon 10 c.c. $\frac{1}{10}$ th of normal phosphate of soda solution, always 2 or 3 $\frac{1}{10}$ c.c. more than 20 c.c., in order to call forth faintly the reaction with ferrocyanide of potassium. In order to make this reaction appear, it is not necessary to add a certain excess of uranium, and therefore I finish off the experiment by the addition of the phosphoric acid-containing fluid until the reaction with ferrocyanide just ceases to be perceptible; and if, for that purpose, a normal solution of phosphate of soda at $\frac{1}{10}$ th be taken instead of the phosphoric acid solution to be tested, it is only required to subtract the number of c.c. employed of that solution from the number of c.c. employed of the uranium solution. The result thus obtained will be undoubtedly nearer to the true relation existing between phosphoric acid and oxide of uranium than when the reaction with ferrocyanide is simply relied on.

In order, however, to determine more accurately the relation existing between the weight of the uranium double salt and phosphoric acid when the former substance is used for the volumetrical determination of the latter, I prepared solutions of the same strength—that is to say, such solutions which by equal bulk contain equal quantities by weight—the experiment being so conducted as to render me independent of balance, measuring vessels, and the influence of varying temperature. The solutions contained 2 grms. of substance for 100 c.c. Ten c.c. of phosphate of soda solution were acidulated with acetic acid and warmed. After the addition of 15 c.c. of the solution of the uranium double salt a very small drop of the fluid gave, on being tested with a very small drop of ferrocyanide solution, a deep brown colouration (the drops of ferrocyanide solution should be kept ready at hand on a small porcelain slab). No reaction was perceptible after the addition of 2 c.c. of the first-named solution; a rather strong reaction was observed after a further addition of 2 c.c. of the second solution; again, after addition of 0.5 c.c. of the first solution a weak reaction, and upon the addition of 0.2 c.c. more of the same solution a very weak reaction was observed; lastly, after the addition of 0.2 c.c. of the same solution all reaction with the ferrocyanide ceased, but 1 drop = $\frac{1}{10}$ th c.c. more of the uranium solution brought about the reaction faintly again. Accordingly,

upon 12.9 c.c. of the first solution 17 c.c. of the second have been applied—that is to say, upon 129 parts by weight of phosphate of soda 170 parts by weight of the double acetate of uranium and soda—taking the equivalent of phosphate of soda, $Na_2H_2PO_8 + 24HO$, at 359, and the formula of reaction—

The quantity of the double salt to be used for the volumetric estimation of phosphoric acid is the number 473; but when 472 ($U = 60$) is the right number, there can only be a very small error, equal, in this instance, and under the premises just stated, to 0.233 per cent of the uranium taken in excess; and since the percentage of phosphoric acid obtained in excess is precisely the same, it is either in the calculation or in the quantity of the solution of the uranium that the required correction can be made.

ON THE

ATOMIC WEIGHTS OF COBALT AND NICKEL.

By RICHARD H. LEA.

THE atomic weights of cobalt and nickel have long been subjects of controversy, but though much time and labour have been spent upon them, the results arrived at are not as satisfactory as could be desired.

Under these circumstances Professor Gibbs suggested to me a new investigation of the subject. Before giving an account of my own methods and results, I will state briefly those of other chemists. Rothhoff,* in 1826, first endeavoured to ascertain the atomic weights of cobalt and nickel. He determined the amount of chlorine in the respective chlorides by means of silver, and, and from a single analysis of each chloride, obtained for cobalt the equivalent 29.55, and for nickel the equivalent 29.60. As the methods of separating the two metals were at that time imperfect, and as but a single analysis was made in each case, Rothhoff's results can hardly be considered as deserving of confidence.

Erdmann† and Marchand, in 1852, determined the atomic weight of nickel by reducing nickelous oxide in hydrogen. Their results varied between 29.1 and 29.3, and they regarded the lower number as more probably correct. It seems at least possible that the nickel they employed contained traces of cobalt. The subject was again taken up by Schneider‡ in 1857. Pure metallic cobalt was prepared by igniting chloride of purpureo-cobalt in hydrogen. The metal was then dissolved in chlorhydric acid and precipitated by sodic carbonate. The carbonate was washed, and then digested with oxalic acid, the resulting oxalate again washed, burnt in a current of oxygen and the oxide reduced by hydrogen. In other portions of the oxalate the carbon was determined by combustion with cupric oxide.

The following tables gives a summary of the results obtained:—

	Oxalate taken.	Cobalt found. Per cent.	Carbon found. Per cent.	Equivalent Co
1.	1.6355 2.3045	32.552	13.024	29.993
2.	1.1070 1.9010	32.619	13.041	30.015
3.	2.3090 4.0580	32.528	13.005	30.014
4.	3.0070 5.3500	52.523	13.014	29.989
			Mean,	30.003

* Poggendorff's Annalen, vol. viii., pp. 184-5.

† Annalen der Pharmacie, vol. lxxii., p. 76.

‡ Poggendorff's Annalen, vol. ci., p. 387.

Determinations of the atomic weights of cobalt and nickel were also made in 1857 by Marignac.* Cobaltous sulphate was purified by repeated crystallisation and a weighed quantity of the salt heated so as to expel the acid. The resulting oxide was then heated with a known weight of silicate of lead so as to expel the excess of oxygen over and above that required to form cobaltous oxide, CoO . The results obtained varied between 29.32 and 29.38.

Crystallised cobaltous chloride dried at 100° was found to retain 1 atom of water. Three determinations of the chlorine in this salt by means of silver gave for the atomic weight of cobalt 29.42 to 29.51. Anhydrous cobaltous chloride was obtained by heating the crystallised salt with sal-ammoniac, in a current of dry chlorine or dry chlorhydric acid gas. The salt almost always, however, left a slight residue insoluble in water. Five analyses of the anhydrous salt gave results varying from 29.36 to 29.42.

In 1859 Dumas† turned his attention to the subject. Perfectly pure metallic cobalt was dissolved in nitromuriatic acid, the solution evaporated to dryness with frequent additions of chlorhydric acid, and the cobaltous chloride submitted to a red heat. In a second preparation from a different sample of metal the chloride was dried *in vacuo*. In this manner the following results were obtained:—

	CoCl ₂ .	Silver.	Equivalent.
1.	2.3520	3.9035	29.57
2.	4.2100	6.9900	29.54
3.	3.5920	5.9600	29.59
4.	2.4920	4.1405	29.50
5.	4.2295	7.0255	29.51

The mean of these five determinations is 29.54. In all cases the chloride was dissolved in boiling water and the solution allowed to cool before precipitating with AgNO_3 . The argentic chloride was reduced in hydrogen. The method employed for the preparation of pure cobalt is not stated.

Russell‡ determined the atomic weights of cobalt and nickel in 1863. Pure metallic cobalt was prepared by igniting chloride of purpureo-cobalt in hydrogen. The metal was dissolved in nitric acid and the solution evaporated and strongly heated. The black oxide obtained was ignited in a current of carbonic dioxide, by which it was converted into light brown cobaltous oxide, CoO , which was then reduced by pure hydrogen. Omitting two trial experiments, the results obtained were as follows:—

	CoO.	Cobalt.	Cobalt pr. ct.
First sample, 1.	2.1211	1.6670	78.591
2.	2.0241	1.5907	78.588
3.	2.1226	1.6673	78.550
4.	1.9947	1.5678	78.598
5.	3.0628	2.4078	78.614
		Mean,	78.588

First specimen twice purified—

1.	2.1167	1.6638	78.603
2.	1.7717	1.3924	78.591
3.	1.7852	1.4030	78.591
		Mean,	78.595

First specimen three times purified—

1.	1.6878	1.3264	78.588
2.	2.2076	1.7350	78.592
		Mean,	78.590

Second specimen—

1.	2.6851	2.1104	78.597
2.	2.1461	1.6868	78.598
		Mean,	78.597

Third specimen—

1.	3.4038	2.6752	78.595
2.	2.2778	1.7901	78.589
3.	2.1837	1.7163	78.596
		Mean,	78.593

The mean of all the results is 78.5926, from which we find for the equivalent of cobalt on the old system 29.37.

In 1866 the subject was taken up by Sommaruga,* who determined the amount of metallic cobalt in chloride of purpureo-cobalt by reduction in a bulb tube with hydrogen. His results were as follows:—

	Salt taken.	Cobalt found.	Equivalent.
1.	0.6656	0.1588	30.002
2.	1.0918	0.2600	29.929
3.	0.9058	0.2160	29.982
4.	1.5895	0.3785	29.926
5.	2.9167	0.6957	29.992
6.	1.8390	0.4378	29.916
7.	2.5010	0.5968	30.009
		Mean,	29.963

Winkler†, in 1867, determined the atomic weight of cobalt by heating a known weight of the metal with a perfectly neutral solution of double chloride of gold and sodium. The cobalt was obtained by the reduction of chloride of purpureo-cobalt.

	Salt taken.	Gold found.	Equivalent of Co (Au=196).
1.	0.5890	1.3045	29.497
2.	0.3147	0.6981	29.451
3.	0.5829	1.2913	29.492
4.	0.5111	1.1312	29.518
5.	0.5821	1.2848	29.522
		Mean,	29.496

Finally, in 1869, Weselsky‡ made a new determination of the atomic weight of cobalt by finding the quantity of metallic cobalt in weighed quantities of cobalti-cyanide of aniline-ammonium and of ammonium. The results were as follows:—

	Cobalt salt.	Cobalt found.	Equivalent
1.	0.8529 gr.	0.1010	29.44
2.	0.6112 "	0.0723	29.38
3.	0.7140 "	0.0850	29.59
4.	0.9420 "	0.1120	29.54
1.	0.7575 "	0.1160	29.46
2.	0.5143 "	0.1130	29.55
		Mean,	29.48

The first four analyses were made with the aniline, the last two with the ammonium salt. These are the only determinations of the atomic weight of cobalt which I have been able to find, and I will therefore pass to my own analyses.

Commercial cobaltic oxide was treated in a large porcelain crucible with enough strong sulphuric acid to make it into a stiff paste. The crucible was then placed in a muffle furnace and heated for some time, at first gently and afterwards to low redness. The sulphate obtained was dissolved, filtered, and submitted for some time to a current of sulphydric acid gas, by which copper, arsenic, &c., were removed. The filtrate was treated with chlorine water to peroxidise the iron present and then allowed to stand for forty-eight hours in contact with baric carbonate, the whole being frequently and thoroughly stirred. In this manner iron and manganese were almost wholly removed. The filtrate was then treated with a large excess of baric carbonate, and cyanhydric acid gas passed into the liquid until the whole of the cobalt was converted into cobalti-cyanide of barium, $\text{Co}_2\text{Cy}_{12}\text{Ba}_3$. The solution of this salt was then boiled with mercuric oxide to separate the nickel present, as NiCy_4Ba , as well as traces of iron and manganese. The mercury was then removed from the filtrate by sulphydric acid gas, and the solution of cobalti-cyanide barium regarded as chemically pure. The methods which I adopted to determine the atomic weight of cobalt do not differ in principle from those of Weselsky and Sommaruga. I first formed cobalti-cyanides of

† Zeitschrift für Anal. Chemie, 1867, p. 18.

‡ Berichte der Deutschen Chem. Gesellschaft, 1870.

alkaloids having high atomic weights and forming highly crystalline and perfectly definite double cyanides. I then determined the water of crystallisation in these salts directly, and afterwards the percentage of cobalt in each. This last was effected by first carefully heating the salt in a platinum crucible by means of a ring-burner, and afterwards burning off the carbon first in air and then in oxygen. Finally the cobalt was reduced to metal by a current of pure hydrogen, and weighed. In this manner but two weighings were necessary. In another series of experiments I determined the amount of metallic cobalt in weighed quantities of chloride of purpureo-cobalt by igniting the salt in a current of pure hydrogen gas. To effect the reduction without loss, I employed an arrangement due to Dr. Gibbs, and consisting of a small thin disk of porous earthenware. The chloride of purpureo-cobalt was placed in a porcelain crucible and the disk of earthenware supported above it by the walls of the crucible. The hydrogen was introduced by a tube passing into the bored cover, and the crucible was then carefully heated from above. In this manner the gas diffused through the porous septum, which in turn served to prevent the escape of any particles of solid substance. The reduction was absolutely complete, and the metal did not oxidise after slowly cooling in an atmosphere of hydrogen. In the analyses made in this manner, also, but two weighings were necessary.

In my first series of experiments I employed only the cobalti-cyanides of brucine and strychnine, the corresponding salts of morphine, narcotine, chinine, and cinchonine having been found difficult to prepare in a state of purity by re-crystallisation. The brucine and strychnine salts were prepared by decomposing the sulphates of these bases with cobalti-cyanide of barium, and repeatedly re-crystallising the salts formed. The brucine salt crystallised in beautiful white, barb-shaped crystals with a high lustre. It was but slightly soluble in cold water, and crystallised with remarkable facility. The strychnine salt was in beautiful, nearly colourless needles, and like the brucine salt crystallised almost completely from its solution on cooling. Six analyses were made with each of these salts.

Of the strychnine salt—

0.7084 gr. dried at 115° C. lost 0.0392 gr. of water = 5.53 per cent. The formula,

requires 5.57 per cent water of crystallisation.

The following are the results of my determinations of the amount of cobalt in this salt :—

No.	Salt taken. Gr.	Cobalt. Gr.	Cobalt. p.c.	At. weight.
1.	0.4255	0.0195	4.5830	59.22
2.	0.4025	0.0185	4.5960	59.36
3.	0.3733	0.0170	4.5540	58.83
4.	0.4535	0.0207	4.5640	58.96
5.	0.2753	0.0126	4.5770	59.14
6.	0.1429	0.0065	4.5490	58.76
		Mean,	4.5705	59.05

The probable error of the mean is ± 0.012 , and the atomic weight of cobalt 59.05, with a probable error of ± 0.156 . In the case of the brucine salt, three determinations of the water of crystallisation were made.

Gr.	Gr.
0.4097 gave 0.0465 water at 117° C. = 11.35 per cent.	
0.3951 " 0.0453 " 119° " = 11.46 "	
0.6653 " 0.0752 " 128° " = 11.30 "	

The mean of these three determinations is 11.37 per cent.

The formula, $\text{Co}_2\text{Cy}_{12}(\text{C}_{23}\text{H}_{26}\text{N}_2\text{O}_4)_6\text{H}_6 + 20\text{OH}_2$, requires 11.39 per cent water of crystallisation.

The results of my determinations of the amount of metal in this salt are as follows :—

	Salt taken. Gr.	Cobalt. Gr.	Cobalt, p.c.	At. weight.
1.	0.4097	0.0154	3.7590	59.41
2.	0.3951	0.0147	3.7200	58.76
3.	0.5456	0.0204	3.7390	59.08
4.	0.4402	0.0165	3.7480	59.22
5.	0.4644	0.0174	3.7470	59.21
6.	0.4027	0.0151	3.7470	59.24
		Mean,	3.7437	59.15

The probable error of the mean is here ± 0.0088 , and the atomic weight of cobalt 59.15, with a probable error of ± 0.146 .

The method of analysing the chloride of purpureo-cobalt has already been described. The results of my analyses are as follows :—

No.	Salt taken. Gr.	Cobalt. Gr.	Cobalt, p.c.	At. weight.
1.	0.9472	0.2233	23.5750	59.07
2.	0.8903	0.2100	23.5870	59.11
3.	0.6084	0.1435	23.5860	59.11
4.	0.6561	0.1547	23.5790	59.08
5.	0.6988	0.1647	23.5690	59.05
6.	0.7010	0.1653	23.5810	59.09
		Mean,	23.5795	59.09

The probable error of the mean is here ± 0.004 , and the calculated atomic weight 59.09 with a probable error of ± 0.0146 .

The mean of my eighteen determinations of the atomic weight of cobalt is 59.10. For the sake of comparison I give here the results obtained by other observers, in tabular form, reduced to the modern scale of atomic weights :—

Rothhoff,	59.10	Russell,	58.74
Schneider,	60.00	Sommaruga,	59.93
Marignac,	58.84 to 59.02	Winkler,	58.99
	58.72 to 28.84	Weselsky,	58.96
Dumas,	59.08	Lee,	59.10

Nickel.—The atomic weight of nickel was also first determined by Rothhoff* in 1826, by determining the amount of chlorine in a weighed quantity of nickelous chloride. A single experiment gave for the equivalent 29.60, a number which is probably too high, in consequence of the imperfection of the processes known at that time for the separation of nickel from cobalt. Erdmann and Marchand took up the subject in 1852†. Nickelous oxide prepared by various processes was reduced in a current of hydrogen and the metal weighed. No data are given, but the authors state that their results varied between 29.1 and 29.3, and that they consider the lower number more probably correct.

Schneider‡, in 1857, also determined the atomic weight of nickel. Pure nickelous oxalate was burnt with cupric oxide to determine the oxalic acid, while the amount of metallic nickel was obtained by reducing the oxide with pure hydrogen. In this manner Schneider obtained as the mean of four analyses the number 29.02.

Marignac||, in 1857, determined the atomic weight of nickel by methods precisely similar to those employed by him in the case of cobalt already cited. His analyses of the sulphate of nickel gave results varying from 29.2 to 29.5, while those of the chloride gave results varying between 29.4 and 29.64. Marignac does not give his method of obtaining pure salts of nickel.

The subject was next investigated by Dumas,§ who determined the quantity of chlorine in nickelous chloride, and obtained for the equivalent of nickel as a mean of five analyses the number 29.514. The author does not give the process by which the nickel was obtained free from cobalt.

Russell,¶ took up the subject of the atomic weight of

* Pogg. Ann. vol. viii., p. 184.

nickel, together with that of cobalt, in 1863. Pure nickelous oxide was first ignited in a current of carbonic dioxide, and afterward in pure hydrogen. His results were as follows:—

- 1st specimen, mean of 3 determinations, 100 parts of oxide gave 78.596 Ni.
2nd specimen, mean of 3 determinations, 100 parts of oxide, gave 78.584 Ni.
3rd specimen, mean of 3 determinations, 100 parts of oxide, gave 78.598 Ni.
4th* specimen, mean of 3 determinations, 100 parts of oxide, gave 78.592 Ni.

The mean of all the determinations gave for the quantity of nickel in 100 parts of the oxide 78.5925, and for the atomic weight of nickel 58.74.

In 1866, Sommaruga† determined the atomic weight of nickel by ascertaining the quantity of sulphuric acid in pure crystallised double sulphate of nickel and potassium. The mean of six analyses gave for the equivalent of nickel the number 29.013, with a probable error of ± 0.079 .

Winkler‡, in 1867, employed the method of reduction already described. The mean of four analyses gave for the equivalent 29.527, with a probable error of ± 0.056 .

With these preliminary statements I pass to an account of my own methods and results. Metallic nickel of commerce was dissolved in nitro-sulphuric acid, and the nitric acid expelled by heat. The sulphate was then dissolved in water and the traces of copper and arsenic removed by a long-continued current of sulphydric acid gas. The iron in the filtrate was then oxidised by means of bromine, and precipitated by agitation with BaCO_3 . The cobalt was removed by potassic nitrite and the nickelous sulphate then converted into nickel-cyanide of potassium, which was re-crystallised. This salt contained only a trace of cobalt after four crystallisations. To determine the atomic weight of nickel I adopted the method already employed to determine that of cobalt. I first formed the double cyanides of nickel with brucine and strychnine, and then determined, first the quantity of water in each of these salts, and afterward the percentage of metallic nickel. This last determination was effected by first carefully heating the salt in a platinum crucible, employing the ring-burner of Dr. Gibbs so as to apply the heat at the rim of the crucible first, and afterward in successive zones until the bottom of the crucible was reached. The remaining carbon was then burned off in a current of pure oxygen, and the oxide of nickel finally reduced by igniting it in carefully purified hydrogen.

The double cyanides of nickel, brucine, and strychnine were prepared by double decomposition, the salts being but slightly soluble in cold water. They were then repeatedly re-crystallised, and when tested by the spectro-scope were found to be absolutely free from potassium. All of these salts crystallised in very pale yellow needles.

My analyses of the brucine salt led to the following results:—

0.4496 gr. dried at 120°C . lost 0.0258 gr. $\text{OH}_2 = 5.738$ per cent water.

The formula $\text{Ni}_3\text{Cy}_{12}(\text{C}_{23}\text{H}_{26}\text{N}_2\text{O}_4)_6\text{H}_6 + 10\text{OH}_2$, requires 5.929 per cent.

No.	Salt taken.	Nickel.	Nickel, p. c.	At. weight.
1.	0.3966	0.02270	5.7240	57.92
2.	0.5638	0.03230	5.7290	57.98
3.	0.4000	0.02300	5.7500	58.20
4.	0.3131	0.01795	5.7330	58.02
5.	0.4412	0.02520	5.7120	57.79
6.	0.4346	0.02490	5.7290	57.98
		Mean,	5.7295	57.98

The probable error of the mean percentage of nickel is ± 0.008 and the atomic weight of nickel 57.98, with a probable error of ± 0.089 .

Six analyses of the strychnine salt were then made.

* Second purification.

0.3399 gr. dried at 112°C . lost 0.0178 gr. water = 5.24 per cent.

The formula $\text{Ni}_3\text{Cy}_{12}(\text{C}_{21}\text{H}_{22}\text{N}_2\text{O}_2)_6\text{H}_6 + 8\text{OH}_2$, requires 5.45 per cent.

No.	Salt taken.	Nickel.	Nickel, p. c.	At. weight.
1.	0.5358	0.0354	6.607	58.15
2.	0.5489	0.0363	6.613	58.21
3.	0.3551	0.0234	6.589	57.98
4.	0.4495	0.0297	6.607	58.15
5.	0.2530	0.0166	6.561	57.72
6.	0.1956	0.0129	6.595	58.04
		Mean,	6.595	58.04

The probable error of the mean percentage of nickel is ± 0.013 , and the atomic weight 58.038, with a probable error of ± 0.119 .

The mean of all my determinations of the atomic weight of nickel is 58.01. The following table gives all the determinations made:—

Rothhoff,	59.20	Dumas,	59.028
Erdmann and	58.20 to	Russell,	58.740
Marchand,	58.60	Sommaruga,	58.026
Schneider,	58.04	Winkler,	59.054
Marignac,	58.40 to 95	Lee,	58.010

In conclusion, my thanks are due to Dr. Gibbs for the selection of the subject of my work, and for his advice during the course of my investigation.—*American Journal of Science.*

ON THE
DETERMINATION OF NITROUS ACID,
WITH SPECIAL REFERENCE TO THE
MANUFACTURE OF OIL OF VITRIOL.*

By W. CROWDER.

In the course of my daily occupation I have had occasion to make some observations at the chambers on the absorption of nitrous acid, and being in want of some rapid but accurate method for determining the quantity in the vitriol from the columns and denitrators, I have endeavoured to devise a good process for accomplishing this object.

I cannot find that there are more than one or two persons on the Tyne who use any quantitative process at all, most managers depending upon the rule-of-thumb method of adding water and judging the amount of absorption by the quantity of gas evolved on admixture.

The only methods with which I am acquainted are the "chloride oflime" and the "urea" processes. The chloride of lime process is in use occasionally, but I cannot find that any attempt has been made to express in terms of nitrous acid or nitrate of soda the percentage of nitrous acid present.

The directions for performing this analysis in Richardson and Ronalds are as follows:—

"A small tube, measuring 20 cubic centimetres, is filled with chloride of soda of 100 Gay-Lussac; its contents are poured into a phial which contains about two-thirds of a pint of distilled water.

"Another glass instrument, measuring 20 cubic centimetres, divided into 200 parts, is filled with nitrous sulphuric acid to be tested, and the acid is gradually poured from it into the phial which contains the solution of chloride of soda until, on adding a few drops of a solution of indigo in sulphuric acid, the blue colour is no longer destroyed. If 17 or 20 parts only have been used, 10 pints of the acid tested will cause a saving of 1 lb. of nitre. The more acid required to destroy the colour of the indigo the less nitrous acid it contains."

I have not used this method, but I hear the results are pretty constant.

* Read before the Newcastle-upon-Tyne Chemical Society.

"Hart's process," by nitrate of urea, is founded upon the fact that urea, when brought in contact with nitrous acid, is instantly decomposed into carbonic acid and nitrogen, thus:—

and upon the fact that nitrous acid decomposes iodide of potassium with liberation of free iodine.

If, therefore, a solution of a known quantity of urea be taken and nitrous vitriol dropped into it, so long as any urea remains undecomposed no reaction of nitrous acid is manifested, but so soon as all the urea is decomposed the nitrous acid produces the well-known reaction upon iodide of potassium, liberates iodine, and in the presence of a solution of starch gives at once the characteristic blue colour of iodide of starch.

The practical part of the process is as follows:—

Twenty grains of nitrate of urea are dissolved in a few ounces of water and the fluid raised to the boil. The nitrous vitriol to be examined is filled into a burette. The solution of urea is removed from the lamp and the nitrous vitriol dropped into it. Brisk effervescence takes place from the evolution of carbonic acid and nitrogen gases; a drop of the fluid is from time to time taken out and added to some drops of solution of iodide of potassium and starch spotted on a white plate. At first the iodine and starch fluid manifest no reaction, but as fresh additions of nitrous vitriol are made to the solution of urea a point is arrived at when the nitrous acid has decomposed all the urea, any further quantity of nitrous acid now remains in the fluid, and a drop of the fluid now added to the spots of iodide and starch develops the colour and indicates the conclusion of the reaction.

The number of graduations of nitrous sulphuric acid used in decomposing the 20 grains of nitrate of urea, indicates at once, by a simple calculation, the quantity of nitrous acid present.

The calculation is based on the fact, that for every 20 grs. of nitrate of urea there would be required 12.35 grs. of nitrous acid, which is equivalent to 27.64 grs. of nitrate of soda.

I have made some enquiries among chemists here, but I cannot find anyone who has succeeded in making it a practical process.

I have tried it myself on the same sample of nitrous vitriol, four times over, but I cannot say that I have been successful, as will be seen by the following results:—

Grs. of nitrate of urea required.	Grs. of nitrous sulphuric acid.
20	334.90
20	190.30
20	187.80
20	327.20

It is possible that I may not have complied with some necessary condition, but I think I have followed the process exactly as laid down in Muspratt's "Chemistry," vol. ii., p. 1040.

There appears to me to be a defect in the process, inasmuch as the reaction is ordered to be effected at a boiling-heat.

Now, on adding nitrous vitriol to a boiling solution of nitrate of urea, a very tumultuous effervescence takes place, and, I think, an error of loss of nitrous acid occurs, and from some cause, which I confess I cannot clearly understand, the reaction of iodine does not manifest itself so soon in some cases as in others, the result being that you cannot hit the mark on two occasions successively. There is a further objection, that the heating of the fluid requires time, and where many samples are to be tested, this becomes an object of some importance.

To obviate these difficulties, I have contrived a plan founded upon this reaction of nitrous acid on urea, which is exceedingly simple and gives very constant results.

I have already shown that in the decomposition of urea by nitrous acid there are formed 2 eqs. of carbonic

acid, 4 eqs. of nitrogen, and 14 eqs. of water. The carbonic acid and nitrogen escape with effervescence, and by suitable appliances may be weighed; the loss of weight will express, by a simple calculation, the quantity of nitrous acid present.

The apparatus required is an ordinary carbonic acid apparatus, in which the moisture is arrested by sulphuric acid, and by which the acid to be tested can be run into the solution of nitrate of urea in a very gentle stream. Such an instrument is described in Fresenius as a Geissler's carbonic acid apparatus. The one I have been using is on the same principle, but slightly modified in details.

The operations are as follows:—

The bottle of the instrument is half filled with water, containing about 20 grs. of urea or 30 grs. nitrate of urea in solution. The instrument is now weighed; the acid tube is filled with the nitrous vitriol, to be tested and weighed again; the difference is the quantity of substance taken.

The tap containing the nitrous vitriol is turned on, and a slow stream of acid falls down through the solution of nitrate of urea to the bottom of the vessel. In the course of a few minutes the acid tube has become empty, the apparatus is shaken to cause complete admixture, and after the violent effervescence which at first takes place is over, the instrument is heated to about 200° to separate all the dissolved gas.

When cold, it is sucked through to remove the gas remaining in the apparatus and weighed.

The difference of weight before and after the operation indicates the quantity of carbonic acid and nitrogen liberated.

The quantity of nitrous vitriol taken is about 300 grs.

The calculation is as follows:—

Therefore, $2\text{CO}_2 + 4\text{N} : 2\text{NO}_3$ quantity of $\text{CO}_2 + \text{N}$ found,

Equiv. = 100 : 76 : X :: nitrous acid found.

The results are very constant, as will be seen by the following analysis of samples of nitrous vitriol:—

	Expt. 1.	Expt. 2.
1st trial, by Dr. Hess ..	3.02	2.62
2nd	3.08	2.60
3rd W. Crowder ..	3.16	2.63
4th	2.35	—

This process seems to me much preferable to the mode of operating with iodide of potassium and starch, and since it is dependent upon a decomposition which is perfectly definite and constant, and the results of which can be most accurately weighed, I am inclined to believe that it is much more to be depended upon than any process in use at present.

I was anxious to institute a comparison between this method and some process dependent upon the oxidation of nitrous acid into hyponitric or nitric acid. Margueritte's process for oxidising proto-into peroxide of iron, suggested itself as one of the best, from the remarkable distinctness with which the point of complete oxidation is indicated; and the rapidity with which it can be performed was a further recommendation.

With this view, I prepared a solution of permanganate of potash in water, of such strength that a burette divided into 1000 grs. measure of water, oxidised a solution containing about 5 grains of iron to peroxide, as in Margueritte's method. Now, to peroxidise protoxide of iron requires the addition of 1 eq. of oxygen to every 2 eqs. of iron.

Therefore, if 2 eqs. Fe : 1 eq. O :: Fe : O.
56 : 8 :: 5 : 0.714.

In the reaction which takes place when permanganate of potash is added to nitrous vitriol, I assume that the whole of the nitro-compounds are there in the form of NO_3 . This is in accordance with the experience of those who have paid any attention to the subject, and I

further assume that this NO_3 in the addition of permanganate of potash is converted into nitric and not hyp-nitric acid.

The above 0.714 gr. of oxygen would, therefore, represent the following quantity of NO_3 :—

The practical process is conducted as follows :—

About 100 to 150 grs. of the nitrous sulphuric acid to be tested is weighed out in a beaker of some 6 oz. capacity. The standard solution of permanganate is poured from the burette, and the number of graduations noted at the point at which the vitriol ceases to decolourise the permanganate.

Care must be taken at the commencement of the operation not to shake the acid and solution, and to keep a little permanganate floating on top of the vitriol, until the vitriol is somewhat diluted, otherwise there is fear of losing a small quantity of nitrous acid by effervescence before it becomes oxidised; this can, however, be very easily managed with ordinary care. The results are perfectly constant, as may be seen by inspection of the tables.

The operation may be varied with advantage for manufacturing purposes by taking a measured quantity of standard solution of permanganate, and dropping into it from a graduated tube, with a pinch-cock, the vitriol to be tested; and it has this great advantage, that it shortens the time, and being done by measure, it involves no trouble or time in weighing.

At the time when I first made these experiments I was not aware that such a plan (although obvious enough) was in use in any laboratory; but on communicating with Mr. Clapham, of the Walker Alkali Works, I found that he had been using this method very successfully for a long time.

From some cause, which I am as yet quite unable to account for, I find that the results obtained by this process are about one-third less than those obtained by the urea method. Whether there is any inaccuracy in the way of calculating and comparing the results I cannot yet discover; but by taking a vitriol containing a known quantity of nitrous acid, as determined by the "urea" process, and standardising the permanganate by that quantity, results are obtained which agree perfectly well with the quantity of NO_3 in other samples as determined by the urea process. It is my intention, as time and opportunity presents itself, to continue the investigation of this very interesting subject of enquiry.

Although a subject of great theoretical interest, it is one which is of considerable practical importance, inasmuch as an accurate method of determining nitrous acid cannot fail to assist a manager in settling many questions of practice about which there is at present great difference of opinion.

Need I further point out the great advantage that the man who works by "rule-of-three" has over the man who works by "rule-of-thumb"?

(To be continued.)

NOTE ON A CUPRIC PHOSPHATE FROM CORNWALL.

By Professor A. H. CHURCH, M.A.

MR. TALLING, of Lostwithiel, forwarded to me some weeks ago specimens of a beautiful mineral, emerald-green to verdigris-green in colour. It occurs on quartz in minute botryoidal forms, and gave on analysis the following percentages :—

Cupric oxide	66.61
Phosphorus pentoxide ..	24.51
Water	8.88

100.00

From these results and others which I shall take occasion to publish before long, this mineral appears to correspond among the phosphates to Cornwallite among the arseniates. It is a rare mineral, so far as Cornish localities are concerned, though I possess a few specimens obtained from old collections.

It is pseudomalachite, var. A. of Dana, and ehrlite of Breithaupt. Its formula is evidently $5\text{CuO} \cdot \text{P}_2\text{O}_5 \cdot 2\text{H}_2\text{O}$, which may be written $\text{Cu}_3\text{P}_2\text{O}_8 + 2\text{CuH}_2\text{O}_2 + \text{aq}$, thus corresponding to that of Cornwallite as revised by me,* namely— $\text{Cu}_3\text{As}_2\text{O}_8 + 2\text{CuH}_2\text{O}_2 + \text{aq}$. The theoretical percentages demanded by the formula proposed for the Cornish copper phosphate (which is now again being raised, I am told) are these :—

CuO	66.98
P ₂ O ₅	23.92
H ₂ O	9.10

100.00

MISCELLANEOUS.

Lectures at the Franklin Institute, 1871-72.—The course of Lectures to be delivered at the Hall of the Franklin Institute, Philadelphia, comprises a series of forty lectures, divided as follows :—"On Physics and Mechanics," by John G. Moore, M.S.; "On General Physics and Acoustics," by Prof. Edwin J. Houston; "On Guns, Gunpowder, and Projectiles," by Lieut. C. E. Dutton; "On the Chemistry of the Earth and of the Vital Process in Animals and Plants," by Prof. Samuel B. Howell, M.D.; "On the History of Alchemy," by William H. Wahl, Ph.D.; "On the Metallurgy of Iron and Steel," by Thomas M. Drown, Ph.D. Besides the lectures enumerated, the Institute has arranged with a number of eminent lecturers for the delivery of a popular course of scientific subjects, for which purpose the Academy of Music has been engaged.

Masses of Meteoric Iron.—At the meeting of the Geological Society held on the 8th inst., there was read a letter from the Embassy at Copenhagen, transmitted by Earl Granville, mentioning that a Swedish scientific expedition, just returned from the coast of Greenland, had brought home a number of masses of meteoric iron found there upon the surface of the ground. These masses varied greatly in size; the largest was said to weigh 25 tons. Mr. David Forbes having recently returned from Stockholm, where he had the opportunity of examining these remarkable masses of native iron, took the opportunity of stating that they had been first discovered last year by the Swedish arctic expedition, which brought back several blocks of considerable size which had been found on the coast of Greenland. The expedition of this year however, has just succeeded in bringing back more than twenty additional specimens, amongst which two were of enormous size. The largest, weighing more than 49,000 Swedish pounds, or about 21 tons English, with a maximum sectional area of about 42 square feet, is now placed in the hall of the Royal Academy of Stockholm; whilst, as a compliment to Denmark, on whose territory they were found, the second largest, weighing 20,000 lbs., or about 9 tons, has been presented to the Museum of Copenhagen. Several of these specimens have been submitted to chemical analysis, which proved them to contain nearly 5 per cent of nickel, with from 1 to 2 per cent of carbon, and to be quite identical in chemical composition with many aërolites of known meteoric origin. When polished and etched by acids, the surface of these masses of metallic iron shows the peculiar figures or markings usually considered characteristic of native iron of meteoric origin. The masses themselves were discovered lying loose on the shore, but immediately resting upon basaltic rocks

(probably of Miocene age), in which they appear to have originally been imbedded; and not only have fragments of similar iron been met with in the basalt, but the basalt itself, upon being examined, is found to contain minute particles of metallic iron, identical in chemical composition with that of the large masses themselves, whilst some of the masses of native iron are observed to enclose fragments of the basalt. As the chemical composition and mineralogical character of these masses of native iron are quite different from those of any iron of terrestrial origin, and altogether identical with those of undoubted meteoric iron, Prof. Nordenskjöld regards them as aërolites, and accounts for their occurrence in the basalt by supposing that they proceeded from a shower of meteorites which had fallen down and buried themselves in the molten basalt during an eruption in the Miocene period. Notwithstanding that these masses of metallic iron were found lying on the shore between the ebb and flow of tide, it has been found, upon their removal to Stockholm, that they perish with extraordinary rapidity, breaking up rapidly and falling to a fine powder. Attempts to preserve them by covering them with a coating of varnish have as yet proved unsuccessful; and it is actually proposed to preserve them from destruction by keeping them in a tank of alcohol. Mr. Maskelyne then stated that the British Museum already possessed a specimen of this native iron, and accounted for its rapid destruction on exposure by the absorption of chlorine from terrestrial sources, which brought about the formation of ferrous chloride. This was particularly marked in the case of the great Melbourne meteorite in the British Museum; he had succeeded in protecting this, as well as the Greenland specimen, by coating them externally, after previously heating them gently, with a varnish made of shellac dissolved in nearly absolute alcohol. He considered it probable that a meteoric mass falling with immense velocity might so shatter itself as to cause some of its fragments to enclose fragments of basalt, and even to impregnate the neighbouring mass of basalt with minute particles of the metallic iron: but he considered the question of meteoric origin could only be decided by examining the same mass of basalt at some greater distance from the stones themselves, so as to prove whether the presence of such metallic iron was actually characteristic of the entire mass of the rock.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

Note. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 16, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Thermo-Chemical Researches on the Energy of the Galvanic Current.—A. Favre.—An instalment of a very excellent and exhaustive essay on this subject, but not suited for useful abstraction; an observation also applying to the following paper:—

Observations on some Points of Spectrum Analysis, and on the Constitution of the Induction Spark.—Lecoq de Boisbaudran.

Researches on the Caloric Coefficients of the Hydro-Electric and Thermo-Electric Currents.—F. M. Reault.—The main result of the author's researches may be summarised as follows:—The heat evolved by an electric current is independent of the nature of the galvanic element; the caloric coefficient, K_e , is the same for all sources of galvanic electricity.

Thermo-Chemical Researches on Ammoniacal Salts.—Dr. Berthelot.—The continuation of this very exhaustive memoir (see *CHEMICAL NEWS*, vol. xxiv., p. 181).

Action of Chlorine upon Various Bodies Belonging to the C_3 Series, and on Substances Isomeric with Trichlorhydrine.—C. Friedel and R. D. Silva.—The authors describe at length a series of experiments, made with the view to prove the isomerism of the compound, $C_3H_3Cl_3$, and next the identity of the two compounds, $C_3H_3Cl_3$, derived from acetone and propylene.

Hot Springs and Scalding Sands of the Maronti District of the Island of Iachia.—A. Kanieri.—The author has written a work on this subject, and proposes to utilise the natural (volcanic) heat for the purpose of evaporating sea-water. The Ancients, from a very remote antiquity, were acquainted with the phenomena here alluded to (the island is situated off Naples), and fable attributed the heat to the convulsions of the giant Typhoeus, killed by lightning by Jupiter, and buried under the rocks of Iachia.

October 23, 1871.

The original papers and memoirs relating to chemistry and collateral sciences published in this number are:—

Thermal Researches on the Electrolysis of the Hydracids.—P. A. Favre.—The second portion of a very lengthy and exhaustive memoir on this subject.

Variable Aspect of the Protuberances and other Remarkable Portions of the Sun's Surface.—Rev. A. Secchi, S.J.—The fifth communication on this subject, this paper being elucidated with woodcuts.

Theory of the Simple Limited Reactions by Inverse Action as Applied to the Metamorphosis of Phosphorus.—G. Lemoine.—A very lengthy algebraico-chemical paper, illustrated with woodcuts.

Industrial Working of a Deposit of Chloride of Potassium near Kalutz (Galicia).—A. Jacot.—It appears that at the locality alluded to there was discovered two years ago a saline deposit, very similar to that of Strassfurth. The kainite of the deposit alluded to consists of:—Sulphate of magnesia, 30.04; chloride of potassium, 29.46; chloride of sodium, 20.67; chloride of calcium, 1.27; total, 81.44 (the remainder upon 100 appears to be impurities, among which is clay). The mass, as brought up from the mine, is broken up, and next ground to a fine powder, then treated with warm water, and the chloride of potassium separated, and, having been dried, is chiefly used to be converted into nitrate of potassa (by means of nitrate of soda) for gunpowder manufacture. Common salt has been obtained at Kalutz for a series of years in quantities of nearly 100 tons daily.

Phosphatic Mineral Deposits in France.—M. J. Dumas.—The author exhibits specimens of a native phosphatic mineral, found near Caylux and Cajarc (Lot) some years ago; similar deposits have been found in the Département of Tarn and Garonne, samples of which gave, on analysis, 32.62 per cent of phosphoric acid, equal to 70.64 per cent of tribasic phosphate of lime. It appears that these deposits are sufficiently extensive to be quarried.

Statico-Chemical Researches on the Phenomena Observed by the Mutual Precipitation of Dilute Solutions of Salts of Silver by Hydrochloric, Hydrobromic, and Hydriodic Acids, and by Chlorides, Bromides, and Iodides.—M. Stas.—This excellent and very exhaustive essay bears especially on Gay-Lussac's process for the assay of silver by the moist way.

Thermo-Chemical Researches on Ammoniacal Salts.—Dr. Berthelot.—Continuation of this essay.

Conversion of the Glucoses into Monatomic and Hexatomic Alcohols.—G. Bouchardat.—The author describes at length how, by the application of sodium amalgam (3 per cent sodium), a solution of glucose yields a mixture of ordinary alcohol and of isopropyl alcohol. Sugar of milk, in concentrated solution, yields by the same process similar products. As regards lactine, the author states that it may be made to yield two different glucoses, one of which forms, by hydrogenation, dulcine, and, by oxidation, mucic acid; while the second yields, by hydrogenation, mannite—

Galactose.

On Hexabromide and Hexachloride of Silicon.—C. Friedel.—Notwithstanding the high scientific merits of this essay, its contents are not suited for useful abstraction.

Method of Determining the Gases which are Formed by the Explosion of Nitro-Glycerine.—L. L'Hôte.—The author introduces nitro-glycerine into an eudiometer tube, wherein a mixture of oxygen and hydrogen is contained. When only a small quantity (6 centigrams) of nitro-glycerine is operated upon, the tube resists the force of the explosion. 1 grm. of perfectly pure nitro-glycerine yields 284 c.c. of gas, composed, in 100 parts, of:—Carbonic acid, 45.72; deutoxide of nitrogen, 20.36; nitrogen, 33.92.

Bulletin de l'Académie Impériale des Sciences de St. Petersburg, Vol. xvi., No. 5, 1871.

This number contains the following paper relating to crystallography:—

Crystals of Cerusite (White-Lead Ore) more Especially as Found in Russia.—N. v. Kokscharow.—Illustrated by magnificently executed engravings. The contents strictly belong to crystallography.

Journal für Gasbeleuchtung und Wasserversorgung, No. 19, 1871.

The contents of this number relate strictly to matters concerning gas- and water-works' engineering and management, but, in speaking of a severe fire at the Darmstadt gas-works in August last, the editor (Dr. Schilling) observes that this fire, originating by lightning falling upon the chimney of the aforesaid gas-works, has proved the inefficiency of lightning conductors, even when, as was the case in this instance, well made and in good working order, in the event of very severe thunderstorms taking place.

Polytechnisches Journal von Dingler, first number for October, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Observations on the Preparation of Malleable Cast-Iron.—Dr. E. F. Diirre.—This paper contains a detailed historico-practical account of a branch of industry which was originally a French invention (Réaumur), but the pig-iron preferably used for making the material is that obtained from the Ulverstone district.

Studies on Blast-Furnaces for the Smelting of Iron Ores.—C. Schinz.—The continuation of this exhaustive memoir, there being added to this portion several tabulated forms exhibiting the average specific heat of fuel.

So-Called Scott's Cement.—F. Schott.—By Scott's cement is understood a peculiar preparation of lime and sulphur, obtained either by exposing lime ignited to redness to the vapours of sulphur, or by passing sulphurous acid over lime at the ordinary temperature. The contents of this very lengthy essay are detailed under the following headings:—Preparation and nature of this cement, which varies in composition (but this may be elucidated by the following percentage figures:—Sulphuric acid, 3.65; lime, 53.70; sulphate of calcium, 13.56; sulphite of lime, 2.09); preparation of the cement from gypsum and lime; the hardening of this cement, and the conditions under which it takes place; practical observations.

Testing of Potatoes by means of a Solution of Common Salt. Dr. W. Schultze.—This paper, elucidated by a series of tabulated forms exhibiting results of experiments, treats on the estimation of the quantity of starch contained in potatoes, by means of the specific gravity of the tubers, as determined by the aid of strong brine.

Les Mondes, October 26, 1871.

This number opens with an exhaustive description of an important work, the first part of which has been just published, viz.—

Physical Atlas of France, Edited by the Observatory of Paris, under the Direction of MM. Delaunay and Marié-Davy.—Without entering into the minute details here described, we quote the main headings of the several divisions of this work (published by MM. Hachette):—Political and administrative divisions of France; the soil and waters of France; climatology, agronomy; industry, commerce, navigation; population.

Most Advantageous Arrangement of Galvanic Batteries.—Count du Moncel.—An algebraico-physical essay.

November 2, 1871.

Production of Hydrogen on the Large Scale.—H. Giffard.—The author's apparatus (not further specified) for the production of hydrogen, by passing steam over red-hot iron has been constructed and tested at M. Flaud's works at Paris. It appears that 2 cubic metres (rather more than 70 cubic English feet) of the gas are generated per minute of time; after awhile, the oxide of iron (the current of steam having been previously shut off) is reduced again to the metallic state, by a current of dry oxide of carbon gas.

Estimation of the Value of Beet-Roots for Sugar Manufacture by Chemical Analysis.—M. Felz.—This essay treats on a method, invented by M. Tolopchine, of determining the value of the beet-root juice by a very sensitive and, for this purpose, expressly constructed areometer.

New Method of Applying Bone-Black in Sugar Refining.—E. Rousseau.—The chief point of interest in this paper is that, instead of granulated black, the author proposes to use the material in the state of powder.

Steam-Boiler Incrustation.—Rev. F. Moigno.—The substance alluded to was found to consist, in 100 parts, of:—Water, 3.0; silica, 6.05; magnesia, 3.67; oxide of copper, 11.90; oxide of iron, 7.50; lime, 20.25; alumina, 2.23; carbonic acid, 14.10; traces of sulphuric acid and chlorine; organic matter, 27.68. The water used to feed the boiler was the condensed steam from boiling beet-root juice.

New Kind of Furnace for Reviving Bone-Black.—M. Derrien.—According to the detailed financial account here given, the furnace alluded to is very economical in use.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 223, July, 1871.

This number contains the following original memoir relating to chemistry and collateral sciences:—

Report on the Bichromate of Potassa Battery in general, and particularly on the Arrangement of MM. Chataux, Delaurier, and Barker.—Th. Count du Moncel.—This interesting paper, illustrated by a series of woodcuts, leads to the following conclusions:—Of all the galvanic elements used in industry and arts, those with bichromate of potassa yield the greatest electro-motive

force, are the most economical, give off no irritating vapours, but are, on the other hand, not very constant, and become strongly polarised. These defects are less marked in the Delaurier element with two liquids, and are also greatly obviated in the Chataux elements with constant discharge (*écoulement continu*); the use of the Chataux element with sand and constant discharge offers peculiar advantages in every respect for electric telegraphy and all similar applications, because this element is for equal force more economical than the Daniell element. The Delaurier element with two liquids may be advantageously used instead of the Bunsen element when strong electric currents are required; in order to obtain a continuous and energetic action with the bichromate of potassa battery, this can only be effected by the use of the air current, as invented and applied by M. Grenet; by the addition of bisulphate of mercury to the bichromate solution in the Chataux element, a very continuous and energetic electric current may be obtained.

Le Moniteur Scientifique Quesneville, No. 355 and 356 (double number), October 1 and 15, 1871.

The original papers and memoirs relating to chemistry and allied sciences in this number are:—

On Anthracen and its Derivatives.—E. Kopp.—The continuation (see *CHEMICAL NEWS*, vol. xiv., p. 120) of the very elaborate and exhaustive essay on this subject, divided into the following sections:—Action of bromine upon anthracen; action of oxidising substances on anthracen; action of chromic acid on anthracen. This essay is to be continued.

Diffusion of Albuminous Liquids when placed in Contact with Distilled Water.—A. Commaille.—The contents of this paper bear strictly upon physiology rather than chemistry, but we call attention to its contents on account of the light it throws upon the active principles in vaccine lymph and other animal fluids.

Second Memoir on the Action of Ammonia upon Phosphorus.—A. Commaille.—This essay describes a series of experiments, under the following headings:—Action of ammonia upon the phosphuret, P_2H ; action of supersaturated solution of liquid ammonia upon phosphorus; action of liquid ammonia upon phosphorus assisted by heat; action of dry ammonia gas upon phosphorus (contrary to what is stated in the "Dictionnaire de Chimie," vol. i., p. 216, dry ammoniacal gas does not exert any other action upon phosphorus than the change that element undergoes by exposure to light); action of carbonate of ammonia upon phosphorus; action of an alcoholic solution of ammonia; action of the last-named assisted by heat; action of water upon the deep green coloured phosphorus, and search for ammonia in that phosphuret or hydroure.

Researches on the Influence of Temperature upon the Optical Rotatory Power of Ordinary Sugar and Inverted Sugar.—C. Tuchschild.—We regret that the contents of this excellent and practical essay are not suited for abstraction, on account of the necessity of reproducing, for the proper understanding of the subject, a series of tabulated formulæ.

Destruction of Torpedoes when placed under Water.—A. Guioot.—This interesting paper embodies the author's ideas on this subject, as communicated to M. le Ministre de la Marine.

NOTES AND QUERIES

Gallic Acid.—(Reply to S. E. P.)—Be kind enough to notice Errata inserted in the same column below your query; then substitute HO to SO_3 in the correct formula. They then become—

Formula (1) is that of gallic acid dried at 100° ; (2), that of crystallised gallic acid. Then follows this little calculation:—

Consequently—

Hugo Tamm's formula = Hugo Schiff's formula.

Divide both members of equation by "Hugo's formula," and you will find that—

Tamm = Schiff.

In other words, the two Hugos agree splendidly together.—HUGO TAMM.

MEETINGS FOR THE WEEK.

MONDAY, Nov. 20th.—London Institution, 4. Prof. Huxley, LL.D., F.R.S., on "Consciousness" (Course of Elementary Physiology).

Medical, 8.

TUESDAY, 21st.—Civil Engineers, 8.

Zoological, 9.

WEDNESDAY, 22nd.—Society of Arts, 8.

Geological, 8.

THURSDAY, 23rd.—London Institution, 7.30. Mr. P. L. Simmonds, F.R.C.I., F.S.S., on "Science and Commerce; Illustrated by the Raw Materials of our Manufactures."

Royal, 8.30.

Philosophical Club, 6.

FRIDAY, 24th.—Quekett Microscopical Club, 8.

TO CORRESPONDENTS.

E. K.—"Elements de Chimie," par M. Victor Regnault (Paris: Victor Masson et Fils), is one of the best for your purpose; as there are several editions be careful to order the last.

C. Claus.—We cannot insert your reply to our querist, "W. S."; it is better adapted for our advertisement columns than for "Notes and Queries."

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

Now ready, Second Edition, much Enlarged, with numerous Engravings, 8vo., 12s.

A Systematic Handbook of Volumetric Analysis; or the Quantitative Estimation of Chemical Substances by Measure, applied to Liquids, Solids, and Gases. By FRANCIS SUTTON, F.C.S., Norwich.

J. and A. Churchill, New Burlington Street.

Now ready, Sixth Edition, with 98 Engravings, fcap. 8vo., 6s. 6d.

Bowman's Practical Chemistry, including Analysis. Edited by C. L. BLOXAM, Professor of Chemistry in King's College, London.

J. and A. Churchill, New Burlington Street.

Now ready, price 4s., with coloured frontispiece of the more important of the Spectra.

Inorganic Chemistry, by the late Professor GEORGE WILSON, of Edinburgh University; thoroughly revised and brought up to the latest state of the Science by H. G. MADAM, M.A., Fellow of Queen's College, Oxford, and Natural Science Master in Eton College.

W. and R. Chambers, London and Edinburgh.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel; Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND Co., 20, King William Street, Strand.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA of HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS: HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2½d., which costs 1s. if made fresh from meat. Cheapest and finest flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar Sold by all Italian Warehousemen, Grocers, Chemists, and Ships' Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT of MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite a certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, and clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian, and other Governments.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE. The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE OF CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

North London School of Chemistry, Pharmacy, &c.

—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical

Latin, &c. Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871—1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

The LATIN CLASS for the reading of Physicians' Prescriptions, Caesar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

ANALYTICAL LABORATORY AND SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HICKIN'S HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufacture, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

THE CHEMICAL NEWS.

VOL. XXIV. No. 626.

ON THE METHOD OF ASSAYING SILVER ADOPTED IN THE ASSAY OFFICES OF H.M. INDIAN MINTS.*

By H. E. BUSTEED, M.D.,
H.M. Madras Army, Officiating Assay Master, Calcutta Mint.

THE process of assaying silver about to be considered is one which (on a large scale, at least) is peculiar to the Indian Mints: it has been in practice in the Calcutta Mint since 1850; it extended thence in course of time to the Bombay Mint, and more recently to the Madras one.

Though it has been favourably reported on, and described more or less fully as an official duty by various assay officers to local Mint Committees, &c., &c., no steps, that I am aware of, have yet been taken towards making more public the manipulatory details of the process.

It has been suggested to me that it might prove not only interesting, but useful to have described the practical working of a system of the utility of which great experience has been afforded in the Indian Mints, as, on assays made by it, an amount of silver bullion reaching on an average the value of over seven millions sterling is annually purchased by these mints, and by it a silver coinage to about the same value annually, is watched over as regards its purity and maintained up to the legal standard of fineness.

I propose, therefore, to give a somewhat detailed account of the process, omitting only the minor steps in the manipulations, which it would be unprofitably tedious to attempt to bring within the compass of a description; practice alone can lead to an acquaintance or can familiarise with these.

To render more intelligible to the general reader the nature and object of this process of assay, and wherein it contrasts with the other methods in more general use, it may be desirable in the first place to allude briefly to the principles on which those other systems depend for their results, avoiding technicalities and details, as a full description of those processes may be found in any work on assaying, and in most works of chemistry and metallurgy.

In general terms, then, it may be said, that the particular duty of an assayer is to ascertain the proportion of pure gold or silver present in any specimen of mixed metal submitted to him for examination, so that from this report the value may be assigned by calculation to the mass which the sample is supposed to fairly represent.

This is done by the separation of the precious metals from the coarser ones with which they may happen to be alloyed.

The most ancient plan for thus separating silver is that by "cupellation" which attains the end in view, owing to the fact that silver resists the action of air, at a high temperature, while the baser metals under identical circumstances become oxidised, and if a certain proportion of lead be present, its very fusible oxide unites with the other oxides produced during the operation and renders them capable of soaking with it into a porous little vessel (made of bone-ash), called a cupel, leaving behind on the surface of each cupel a glistening button of

pure metallic silver, whose weight can be accurately ascertained.

A certain weight of the specimen of the metal to be assayed is folded up in a certain proportion of thin lead and placed on a cupel. The operation is conducted in a suitable oven (called a "muffle") and furnace. When the remaining little button of silver has cooled, it is weighed and the loss of weight of the specimen operated on represents the baser metals that have been removed; thus, if the specimen weighed 20 grs. and the resulting bead of pure metal weighs 15 grs., the mass would be reported to contain 75 per cent of pure silver.

Several contingencies, however, and collateral circumstances (known to assayers) tend to modify the result of an assay by cupellation, and the assayer has to consider them all in arranging his compensation; failing this the report would be most erroneous; everything, therefore, depends on his skill and experience; but even in the hands of the most experienced and the most skilful the result will fall short of accuracy, and a margin for error must be left, owing to unavoidable imperfection in the assay: the average range of this error ought not, however, to exceed $\frac{1}{4}$ dwt. (12 grs.) in the lb. troy, or say 2 parts in 1000; so that this method is sufficiently accurate for keeping a coinage tolerably close to "standard" and even well within the legal limits on either side of it.

The assay report furnished by it, however, is too remote from accuracy, i. e., is not within sufficiently narrow limits to fairly regulate the valuation of merchants' bullion with satisfaction to seller or buyer, the latter being, in this country, almost invariably the mint.†

The above was the method of assay prevailing in this mint up to 1850. Though it is still practised by many English assayers of great skill, it has been almost entirely superseded on the Continent in consequence of its shortcoming by one contrived by Gay-Lussac, which is less dependent on the individual operator.

This, known as *La voie humide*, or the volumetric process for ascertaining the fineness of silver bullion, consists in precipitating the silver as an insoluble chloride from the solution in nitric acid of a certain weight of the metal to be examined, and in effecting this by the use of a solution of common salt (chloride of sodium), containing a known proportion of salt; this is added gradually till just sufficient has been used to throw down the whole of the silver present as chloride; as chlorine unites with silver in definite chemical proportion, the amount of silver present can be easily and accurately estimated by merely ascertaining the amount of salt which has been exactly necessary to convert the whole of it into chloride of silver.

This is the method practised at the Paris Mint, and by the eminent outside assayers to the Royal Mint of Great Britain, and I believe at most of the European and American Mints.

Assays can be confidently made by it to $\frac{1}{4}$ dwt. or about 6 grains in the pound troy, or even indeed to half this, say to $\frac{1}{2}$ part (0.5) in 1000.

The volumetric system is especially applicable where the silver to be assayed by it is alloyed with copper only, and where the fineness is approximately known beforehand; both these conditions to its successful usage exist

* Should gold or platinum happen to be present in the specimen assayed, as they also resist oxidation, they remain behind, included in the "button," and are, under ordinary circumstances, estimated as silver.

† It being impossible in the operations of a mint to produce a certain mixture of metals (such as silver and copper) with mathematical accuracy, a certain deviation is allowed above or below the legal standard. In India this deviation or "remedy" in fineness is 1 dwt. in the pound troy, i. e. 1-220th part, equal to about $\frac{1}{4}$ parts in 1000.

PS. Since this paper was read, a Legislative Act of the Government of India has been promulgated which declares that the remedy in fineness is not to exceed 2 thousandths for the rupee and half rupee, and 3 thousandths in the case of the smaller silver coins.

‡ That is, the mint receives the bullion in bulk and returns it in coin, a certain seignorage to cover expenses being deducted.

* From the *Journal of the Asiatic Society of Bengal*.
Average for last 20 years.

in such mints, where the only silver assays made are those of metal already alligoted for coinage to the legal standard.

It is acknowledged by its advocates that the presence of mercury in the alloy would materially interfere with the accuracy of the assay, and a certain (rather tedious) modification of the process is essential to avoid error under such a contingency.

Its adoption in the Indian Mints was not considered desirable by their assay officers for reasons of which the following are a few:—

1. A vast amount of the silver which comes to the Indian mints, (viz., China and Rangoon Sycee, bazaar cake silver, Japanese coins, &c.,) contains not only mercury, but lead and other coarse metals.

2. No sufficiently approximate idea of the fineness of such silver can be formed beforehand, thus necessitating a preliminary assay by cupellation.

3. The high temperature of an Indian climate renders it impossible to retain the solution of salt at an uniform strength for any length of time; the evaporation and concentration derange the equivalence which it is essential to maintain between it and the proportion of silver meant to be precipitated by it; thus involving very frequent tedious testing to ascertain daily the actual strength of the standard solution.

4. The whole of the important manipulations should be gone through by the assay master himself or his deputy, a labour beyond their strength in this climate with a very large daily number of assays of various finenesses; and one which would preclude the possibility of his attending to the many other important duties which devolve on the head of an assay office to a mint in India.

The method of assay by cupellation, then, not being accurate enough for the requirements of trade, and that by the French process being considered unsuited to the peculiar work devolving on the assay officers of the mints in India (where there are no bullion refineries), it became necessary here to adapt and introduce a system more likely to fulfil all the objects required of it.

In the volumetric system it has been seen that the proportion of silver present in a mixed metal is estimated by ascertaining the exact amount of salt which it took to precipitate it in the form of chloride of silver; the same end can be attained by collecting, drying, and weighing the chloride itself. One hundred parts of it represent 75.3 of pure (metallic) silver.

Hitherto this process when resorted to at all seems to have been restricted to a very limited application; such as a solitary analysis for some special purpose, possibly the examination of a standard "trial-plate" where the greatest accuracy was required, or perhaps an assayer would resort to it as a delicate confirmatory test of one or two of his assays by the volumetric method.

Some books which go into the principles and details of the assaying of silver, make no mention of it whatever; others allude to it merely to dismiss it as "tedious and less exact" (than the French process). In theory, the process is allowed by all to have the merits of accuracy and simplicity, but it is implied that the tediousness and difficulties of the manipulations (supposed to be) necessary to the carrying out of the theory, detract materially from its practical value; certainly the few details of the manipulations occasionally given, such as the weighing the chloride of each assay (after collecting on a filter and fusion)* in a porcelain capsule, previously counterpoised, were calculated to deter from the idea of this process being ever made available for the assay of silver on a large scale.

The credit is due to Mr. J. Dodd, a former assay master of the Calcutta Mint (and a surgeon in the Madras army), of having encountered those difficulties of mani-

* Of course in practice it would be necessary periodically to recover the silver (by reducing it to the metallic state) from the closely attached fused chloride in each capsule,—a very tedious measure.

pulation, and of having overcome them, inasmuch as he modified and simplified them, and in short so systematised the whole practical working of the process as to render its application to the assaying of silver, to any amount, easy, accurate and economical.

That this result was not attained without much labour and much patient investigation, and that his successors in office acknowledge their deep obligation to Mr. Dodd's intelligent industry, will be apparent from the officially recorded testimony of two of them, which I think it due to him and to them not to withhold, when making mention of the practical carrying-out of this method of assay. Viz., Sir Wm. O'Shaughnessy, who was deputy assay master of the Calcutta Mint in Mr. Dodd's time, and himself a practical chemist of high reputation, writes in April, 1852:—

"Previous to making overcharge of the assay office to Dr. Shaw on the occasion of my proceeding to England on duty, I deem it an act of justice towards the assay master, Mr. James Dodd to place upon record an acknowledgment of the eminent service Dr. Dodd has rendered to the assay department and to the art of assaying generally by his investigation of the analytical process for assaying silver, his improvements in the manipulation of the process, and his admirable system of arrangement which renders it capable of effecting in 24 hours more assays of silver than the mint can ever require in that time."

Dr. Shekleton, the present assay master (now on leave), an assayer of long experience, when giving officially to the Mint Committee at their request a detailed statement of the process says (April, 1855):—

"It would be quite impossible, however, by any mere description to form an adequate idea of the eloquence of the process, or the perfection to which it has been brought by the skill and unwearied industry of Mr. Dodd, late assay master. To him is due, not only the merit of its introduction, but the removal of every practical difficulty in its working; the confidence with which his system has been adopted by all his successors is the highest tribute to its completeness and efficiency."

Method of Assaying Silver by the "Chloride process" (as conducted in the Calcutta Mint) given somewhat in detail.

The samples (or "musters") for assay are, to save time, first approximately weighed by an assistant; they are then placed (each sample in duplicate) in small shallow saucers of polished copper, and so brought in batches of 40 on a board, containing in numerical order receptacles for the little saucer, to the assay master who, in the delicate assay balance, exactly brings each sample to the one required weight.†

As each sample is weighed, it is transferred from the platinum skiff of the balance to a bottle on the left hand of the assayer, by means of a small copper funnel. The bottles for this purpose are held in readiness for the musters by an assistant, and, on receiving them, are removed into the laboratory in batches of six.

On being taken to the laboratory, they are ranged on a circular platform or turn-table, and there one of the (European) assistants adds by means of a pipette $1\frac{1}{2}$ drms. of nitric acid to each bottle, which are then (without their stoppers) transferred to a sand-bath and exposed to a considerable degree of heat, till solution of the contents is effected.

The specific gravity of the nitric acid used is generally 1200, i. e., in the case of known alloys of only copper and silver, such as the standard meltings, coins, &c., but when

* When in the Madras Mint, I remember seeing recorded similar testimony from Dr. Shaw, the assay master, when describing the process on recommending to the Madras Government its adoption in his office.

† The amount of this weight will be more particularly referred to further on.

‡ The chief appliances will be described more fully in an appendix.

the nature of the alloy is uncertain, such as bazaar silver, or some sycee (where the presence of mercury may be suspected), a stronger acid of sp. gr. 1.320 is used. It has been found, too, by experience that the chlorides from fine bar silver eventuate better when the solution has been effected in the stronger acid.

When the samples have been completely dissolved,* the bottles are brought back to the platform and there each receives through a glass funnel† about six ounces of cold distilled water.

There is then added to each bottle through a glass pipette as before 1½ drms. of hydrochloric acid, sp. gr. 1.060, which immediately converts the silver present into the characteristic white precipitate of chloride of silver, which forms in slow-falling curdy volumes.

The stoppers (previously dipped in distilled water) are then carefully replaced, and the bottles are allowed to stand for five minutes.

The bottles are next well shaken two and two by the laboratory workmen for three or four minutes till the chloride aggregates and rapidly falls down; any particles which may retain attached to the neck or upper part of the bottles are washed down by a quick circular motion, and more distilled water being added to within about two inches of the neck (great caution being observed in removing and returning the stoppers), the bottles are then allowed to rest each in its assigned place on the platform for four hours.

At the expiration of that period, the clear supernatant liquid (blue-coloured when copper is present) is removed by a glass syphon, which is lowered to within an inch of the deposited chloride, the greatest care being taken that none of it is drawn up into the syphon. As each platform is made to revolve on its centre, according as each bottle is syphoned, the operator sitting in one place brings the platform round till the next bottle in order gets under the syphon, which is thus in rotation lowered into each. The fluid escapes from the long leg of the syphon through a funnel fitted in the table to a jar placed underneath.

After the first syphoning, the bottles are immediately filled again with distilled water, and each gets a quiet circular motion for a few moments, and the precipitate is again allowed to settle as evenly as possible; this time it will be sufficient to allow them to rest for two hours, when they are again syphoned as before and the stoppers returned.

Under ordinary circumstances these two washings are sufficient, but if the silver is evidently "coarse," a third or fourth washing is similarly given.

When it is considered that the chlorides have been sufficiently washed, the bottles are placed for half an hour in a reclining position on their platforms; this causes the chloride to fall and settle to one spot and renders its removal from the bottles more easy.

Meantime a pneumatic trough has been got ready, capable of containing a batch of twenty inverted bottles; the trough is filled with distilled water; for each bottle there is placed on the floor of the trough a small porcelain saucer holding a little Wedgwood crucible or cup, each numbered to correspond to the bottles. A laboratory workman then removes the stoppers from the bottles and hands them one by one to an assistant at the trough, who, placing his forefinger over the mouth of each bottle inverts it over its corresponding cup, and does not remove his finger till the neck of the bottle has passed down through the water and well into the cup; then the finger being taken away the bulk of the chloride falls by its own weight to the bottom of the cup.

The bottle is held in the position by two rings, one (the larger) above the other, which are fixed to the sides of the trough; this arrangement retains each bottle in

situ, at the proper slant, and admits of the operator gently revolving or slightly raising the bottle with his left hand, while with the right he patiently taps the bottom and sides till the whole of the chloride has been dexterously got out; the finger is then again placed over the mouth and the bottle raised up through the rings and handed (mouth upwards) to the assayer, or to the supervising assistant standing by, who carefully examines it to see that every particle of chloride has been dropped into the cup. When this part of the manipulation has been neatly done, none of the chloride falls over into the saucer which is placed as a precautionary measure under each cup.

When the chloride falls into the cup, it is in an uneven lumpy state and not in a favourable condition for being uniformly dried; it has, therefore, next to be broken up. For this purpose the cups (containing the chlorides, and water to the brim) on removal from the trough are taken in batches on a tray to an assistant seated at a steady table, who first carefully decants off about half the water, and then with a finely polished glass rod (four inches long and one-third of an inch thick) gently stirs and beats the lumpy precipitate, while revolving the cup on the table; this causes it to lie evenly and loosely at the bottom of the cup as a purplish grey powder, not too fine.

He next washes the rod over the cup with distilled water from a drop bottle, lest any of the chloride may be adhering to it, and sprinkles a drop or two from it on to the surface of the water in each cup, so as to cause to sink any minute particles that may happen to remain floating. He then, after an interval of ten minutes, drains off about three-fourths of the supernatant water, which he lets run down the rod into a vessel near him, and with a tap or two with the rod to the outside of the cup to still further loosen the deposit, this part of the manipulation is concluded.

The crucibles are next taken to the drying furnace, where a steam bath is ready to receive them; on the perforated upper plate of this they are ranged, and allowed to remain for about an hour. This gradually, and without spurting, frees the chlorides from moisture, which may be known by their caking, *i. e.*, leaving the sides of the cups round the edges and forming at the bottom of each a loose cake, resembling somewhat a gun-wad. The crucibles are then arranged on a hot air plate and there exposed to a temperature of between 300° and 350° (F.) for about two hours, till thoroughly dried, when they are ready for weighing.† When the above manipulations have been carefully and satisfactorily gone through, each little cup contains an unbroken, tolerably firm, cake of chloride of silver, lying unattached, which admits of being easily grasped with a pair of forceps, and cleanly lifted out of the cup and conveyed to the skiff of the assay balance in which it is weighed. The cups are generally brought from the laboratory to the assayer at the balance in batches of eight or ten. A "standard," synthetically prepared of pure silver and copper, and an assay pound of pure silver are introduced with each day's set of assays, and their chlorides dried with the others, and the analysis of them verified before weighing the rest. Occasionally these "checks" are also fused and weighed in a porcelain capsule, but the weight found never differs from that of the chloride merely dried as above.

Once or twice a month, the silver is recovered from the accumulated chlorides, which are well pounded in a mortar and brought to a powder and then mixed with a proper proportion of chalk and charcoal, and put into a wrought-iron crucible and reduced with heat. The metallic silver so recovered is transferred to the mint.

Under the circumstances of the solution and of the precipitation as detailed above, should any gold happen to be present in the sample operated on, it is not dissolved, and, therefore, becomes entangled with the precipitated

* A slight residuum of gold as a black powder is very generally seen.

† The portion of this which enters the neck of the bottle is protected, or sheathed, with an inch of India-rubber tubing to prevent chipping, if struck against the neck of the bottle.

* The chlorides are weighed warm, to obviate the risk of their absorbing moisture; a precaution especially necessary in the heavy monsoon weather in this country.

chloride of silver and dried and weighed with it, and accordingly comes to be regarded and valued as silver. In this the chloride process resembles that by cupellation, which likewise takes no distinguishing cognisance of gold, and both these processes contrast in this respect with the volumetric one, which is a rigid analysis for silver alone; so that, strictly speaking, an assay conducted by either of the first named methods ascertains the proportion present of "the precious metals," i. e., silver and gold.*

Should mercury be present it does not interfere with the result, when the solution has been effected in excess of citric acid with strong heat. Thus the mercury becomes peroxidised, and hydrochloric acid forms no precipitate in solutions of mercuric salts; any mercuric chloride resulting from the combination would remain in solution and be washed away in the course of the process.

Should lead happen to be present, hydrochloric acid gives no precipitate in a dilute solution, the chloride of lead being soluble in a certain proportion of distilled water; but even were the proportion of lead to silver tolerably large, and the chloride of lead happened to be thrown down, the repeated washings would dissolve and get rid of it.

(To be continued.)

AND THEIR BEARINGS ON THE THEORIES OF THE ORIGIN
OF, AND CONDITIONS ESSENTIAL TO, LIFE.†

By W. H. WOOD.

1. In all cases of original scientific research, the investigator sets before his mind's eye the attainment of one or more of several results. He either wishes by his experiments to train his mind to the observance of phenomena and to the deduction and induction of results therefrom, the truths arrived at being, in this case, only of secondary importance; or he wishes, by such research, to augment the amount of truth and knowledge of the particular branch of science with which his research stands connected. Added to these may be the desire to apply the results so obtained in the arts and manufactures either for general or personal benefit. The love of scientific research for its own sake, without the wish to apply it at all to ulterior purposes, must for ever stand pre-eminent over researches made for any other end, for we consider the discovery of the truth, both scientific and otherwise, to be the duty as well as the highest aim and the noblest occupation in which man can engage.

2. The experiments about to be detailed were made with the intention of giving the experimenter a training, to some extent, such as has just been indicated, but at the same time the importance of the truths to be discovered was not considered as standing in the second place, but as being of equal, if not of greater moment.

3. It has long been known to chemists that aqueous solutions of tartaric acid exhibit—at a shorter or longer time after their preparation—signs of decomposition, as indicated by the growth of fungi, and the production of a small quantity of acetic acid in them. That this fact is generally known, will, I think, be evident from the following quotations:—

* Much of the silver which finds its way to the Indian mints is rich in gold; for instance, sycee contains on an average somewhat about 12 grs. in the Troy pound. This in minting operations is considered as silver, and as such it enters into the coinage. There being as yet no refineries established here, through which such silver could pass to the mechanical departments of the mints the silver coins made during a period when a heavy importation of sycee had been worked up, contain as much as 4 or 6 grs. of gold in every 32 tolas or 1 pound Troy.

† From the *Transactions of the Cleveland Literary and Philosophical Society*.

(a). The late Professor Miller, in his "Chemistry," vol. iii., p. 438, 3rd edition, says: "Its aqueous solution becomes mouldy when long kept, and is slowly converted into acetic acid."

(b). Richardson and Watts's "Chemical Technology," vol. i., part v., p. 163, says: "The solution becomes mouldy by keeping, producing a small quantity of acetic acid."

(c). Watts's "Dictionary of Chemistry," vol. v., p. 677, says: "The aqueous solution becomes covered, after a while, with a fungous growth."

These quotations might be greatly multiplied, but we think sufficient have been given to show that the fact above stated is generally known. Anyone, moreover, who has had a moderate amount of practice in chemical analysis must have proved the truth of this statement many times; and it was from coming in contact again and again with such solutions, that I was led three-and-a-half years ago—simply from a desire to extend the domain of truth, and to train my faculties of observation and reasoning—to commence the course of experiments, some of which, with their results and deductions drawn from them, I intend to describe to you this evening.

4. My first experiments were made on July 18th, 1867. About two ounces of solution of tartaric acid was made by boiling 1 ounce of crystals of the acid in Halifax town's water as drawn from the tap. The solution was filtered, and divided into two portions of about an ounce each, and these placed in 2-oz. stoppered bottles, marked A. and B. To A. two drops of creosote were added, while B. was not subjected to any further treatment. These solutions are before you (part of B. has been used for another experiment), and you will see that up to the present, no formation of fungi or mould has occurred in either. The conclusion therefore seems warrantable from these experiments, that boiling the solution prevents the development of fungi.

5. This conclusion was—ten months after preparing the solutions just described, viz., on May 22nd, 1868—put to the test of experiment, in order to prove its truth or falsity. For this purpose three solutions of the acid were made with the same kind of water as before: No. 1 solution, by dissolving 40 grs. of acid in 1 oz. of the water, and filtering the solution without even warming; No. 2 solution, by dissolving the same amount of acid (40 grs.) in the same quantity of water (1 oz.), which had just been boiled, and was still hot, filtering as before; No. 3 solution was of the same strength as Nos. 1 and 2, but the solution was boiled for a few minutes, and then filtered. These solutions are also before you, and you will observe that while No. 1 solution contains—what was some time ago white mould with brownish nuclei—but which has now become almost entirely brownish, Nos. 2 and 3 solutions contain only a slight amount of sediment, without the least appearance of fungi. From this it is evident that boiling the solutions does prevent the development or formation of the fungi or mould. This treatment of the solutions (viz., the boiling), has, in every case but one in which it has been tried, been found to be efficacious; the case in which fungi have developed, even after boiling, is possibly explainable on certain grounds, as I shall endeavour to show, as also, maybe, a case in which an un-boiled solution has not developed fungi.

6. The next solution before you (to take them in the order of their preparation)—and I should state that I shall only describe these, though they are not more than one-half of the solutions I have prepared,—is marked B, and is one of three experimented with on August 12th, 1868. A mouldy solution of the acid was filtered and divided into two portions marked B. and C. B. was not heated, and has, as you see, again developed fungi, while C. (see Appendix), which is at Halifax, had not, the last time I saw it, developed any.

7. The question suggested itself to my mind, as to whether exposure to light had any influence upon the development of the fungi. To determine this point, I made

on the 21st of September, 1868, two solutions (Nos. 1 and 2) of which No. 1 is before you, by dissolving 20 grs. of the acid in 240 grs. of Halifax water in the cold. The solutions were filtered, and No. 1 was exposed to light, while No. 2 was shut up in a dark cupboard. When examined on the 11th of January, 1869, No. 1 had developed fungi, while No. 2 had not. No. 2 being at Halifax, I cannot state positively whether fungi have developed yet or not (see Appendix). Anyhow, it is evident from these experiments that exposure to light does cause the fungi to develop more rapidly if it is not essential to their development.

8. The character of the water employed next suggested itself as possibly influencing the development of the fungi. To ascertain to what extent this possible cause operated, I made three solutions with Manchester water in the laboratory of Owen's College, in December, 1868, and January 1869, as follows:—Two solutions were made (the proportion of acid to water not being noted) with distilled Manchester water. No. 1 was filtered but not heated; No. 2 was filtered and boiled (time of boiling not noted), and a third solution (No. 3) was made in undistilled and unboiled water, the solution being filtered. No. 1 solution has, as you see, undergone the usual change; No. 2, which was (as I have just stated) boiled, has, notwithstanding this, developed fungi, though in much smaller quantity than No. 1 solution, while No. 3 solution, which should, according to previous trials, develop them most readily, has not done so at all even yet, and, therefore, I shall have to remark on the two latter solutions specially.

9. A further series of experiments on this point (*i.e.*, to determine the influence exerted by the kind or quality of water used), I have made since coming to Middlesbrough. This last series of experiments has been conducted by the light of the experiments already described (as well as others), and modifications have been made in the mode of experiment which are not altogether unimportant.

Instead of the solutions being stoppered or corked up in bottles—so that contact with the outer air is only possible when the stoppers or corks are removed—these solutions have, as you see, been filtered into flasks, over the mouths of which (with two exceptions purposely left exposed), loosely-fitting watch-glasses have been placed. By this contrivance the introduction of dust into the solutions is prevented, while the air has (when alterations of temperature and pressure occur), comparatively free ingress and egress. The flasks were cleaned before use, by shaking some sulphuric acid in them, to destroy organic matters, &c., and were then washed out six times with filtered steam water. The solutions are all of the same strength, *viz.*—10 grms. of the acid to 50 grms. (or c.c.) of either Middlesbrough water or filtered steam water. They were prepared on the 9th of January, 1871, and numbered 1 to 6. They were then subjected to the following treatment:—

- | | | |
|------------------------|---|--|
| Middlesbrough Water. | { | No. 1, left exposed to the air and dust after being filtered and then boiled for five minutes. |
| | | " 2, covered after filtration. |
| | | " 3, covered after filtration, and boiled for five minutes. |
| Steam Water, filtered. | { | " 4, left exposed to air and dust, after being filtered and then boiled for five minutes. |
| | | " 5, covered after filtration. |
| | | " 6, covered after filtration and then boiled for five minutes. |

No growth or formation of fungi has yet occurred; the strength of the solutions appears to exercise some influence on the length of time required before the fungi make their appearance, but its exact bearing on the point has yet to be decided by further experiments.

10. *Citric Acid*.—An acid contained in the juices of the citron, lemon, orange, &c., and which is closely allied to

tartaric acid, exhibits like it, similar phenomena in aqueous solution. The application of the knowledge gained as to tartaric acid solutions, to solutions of citric acid follows, therefore, in natural sequence. I have, accordingly, prepared two solutions of citric acid, and find so far, that the law (if we may dignify it by the name) applicable to tartaric acid solutions, *viz.*, that boiling the solutions prevent subsequent decomposition, holds good for citric acid solutions. For, of the two solutions before you (prepared January 10th, 1871, and numbered 1 and 2), by dissolving 10 grms. of the acid in 100 grms. (c.c.) of Middlesbrough water, filtering, &c., and placing them in flasks (uncleaned by sulphuric acid, simply washed with water of kind to be used). No. 1 was filtered and left unheated, while No. 2 was filtered and then boiled for ten minutes. No. 1 has begun to develop fungi, No. 2 has not. The fungi in No. 1 solution may be well seen—as to their structure—by holding the flask between the eye and the light; they then appear as white semi-transparent globular bodies, fibrous, as if radiated from a central nucleus.

11. It was suggested to my mind that it might be possible to prevent the growth of these low forms of life in tartaric acid solutions, by re-crystallising the acid from a hot solution. Accordingly, I dissolved some crystals of the acid in hot steam water, and evaporated the solution on a sand-bath. It is somewhat difficult without constant watching to get crystals of the acid by this plan, as since the acid itself melts, it is not easy to say when the liquid has been sufficiently evaporated; the evaporation may, consequently, be continued after all the water has evaporated, the result being that the acid is, to a greater or less extent decomposed, as evidenced by the odour of burnt sugar evolved. The acid used in preparing the solution for this experiment was accidentally allowed to evaporate to this extent, and, therefore, I do not lay much stress or put much value on the result which it shows. The re-crystallised acid was dissolved in cold steam water without any filtering or heating. None of the usual appearances have yet presented themselves; but this cannot, as already stated, be considered quite a fair trial; consequently, I intend to make further experiments to elucidate this point.

12. The formation or growth of fungi in the boiled solution already spoken of may, I think, be accounted for on the ground of insufficient boiling—the time was not noted, but was not continued (so far as my memory serves me), for any great length of time. This explanation is borne out by the fact that a less considerable quantity of fungi are found in it than in the solution made at the same time which was unboiled, and this we should naturally expect to be the case. The other real or apparent exception to the general principle which I have endeavoured to establish is the third solution prepared at the same time as the one just mentioned. It was made, as already stated, with Manchester water, undistilled, and the solution was not heated, but simply filtered and corked up in the bottle. The explanation in this case I cannot as yet arrive at, I therefore leave it for further experiments to throw light upon.

13. Having now described the whole of the tartaric and citric acid solutions before you, I must attempt to trace out, as far as possible, the bearing of the results obtained on the questions of the origin of, and the conditions essential to, life. You are doubtless aware that at the present day there are two theories of the origin of life before the world, *viz.*: Biogenesis, or, to quote Professor Huxley's words, the theory "that living matter always arises by the agency of pre-existing living matter;" and Abiogenesis, the theory "that living matter may be produced by not living matter." Professor Huxley in his address to the British Association at Liverpool last year, showed that the evidence, both direct and indirect, in favour of Biogenesis is of great weight, though he carefully guards himself against supposing that "no such thing as Abiogenesis ever has taken place in the past, or

ever will take place in the future." Indeed, he says, "if it were given me to look beyond the abyss of geologically-recorded time to the still more remote period when the earth was passing through physical and chemical conditions, which it can no more see again than a man can recall his infancy, I should expect to be a witness of the evolution of living protoplasm from not-living matter. I should expect to see it appear under forms of great simplicity, endowed, like existing fungi, with the power of determining the formation of new protoplasm from such matters as ammonium carbonates, oxalates and tartrates, alkaline and earthy phosphates, and water, without the aid of light. That is the expectation to which analogical reasoning leads me (Professor Huxley); but I beg you once more to recollect that I have no right to call my opinion anything but an act of philosophical faith."

14. To which, then, of the two theories do the results arrived at lend support? To Biogenesis or Abiogenesis? Most decidedly they support the Biogenesis theory. Let us suppose for a moment that this theory is true, what should we expect beforehand would be the result of boiling the tartaric acid solutions? We should expect—since it is known that living matter generally is killed by being raised to a high temperature—that any living matter which the solutions before described contained would be killed, and, therefore, that no forms of life would make their appearance in such solutions afterwards—an expectation which is confirmed by actual experiment. On the other hand, let us suppose that Abiogenesis is true: how can it be explained that the simple ebullition of our solutions prevents the development of living matter? No change has occurred in the solutions which can be shown to prevent matter developing into living forms, and that being so, we are led to decide that Abiogenesis does not occur at the present day. Nor do we see reason for Professor Huxley's expectation already quoted; seeing, that, unless the existence of a lawgiver be granted, on which Professor Huxley is silent,—we must conclude that the laws governing matter were the same at the period referred to as at the present day; and this being so, if it were possible to transport our boiled solutions to such a distant period, we should find that they would remain the same as at present, no forms of life appearing in them. The same line of argument holds good against the expectation that living matter may be produced from brute matter at any time in the future. Pressing our argument still further we are led to the conclusion that, since dead matter cannot of itself develop living matter, and since life was and is developed, there was, and is, a lawgiver and a life-giver.

15. Leaving this point of the origin, and passing to our other point—the conditions essential to life—we are led to notice a remarkable conclusion recently arrived at by Professor Frankland. This eminent chemist comes to the conclusion, from a series of experiments on effluent sewage-water, and on water for domestic purposes (see CHEMICAL NEWS, vol. xxiii., pp. 67 and 78, January, 1871, for the paper on "The Development of Fungi in Potable Waters"), that the statement of the German philosopher who said "Ohne Phosphor kein Gedanke"—(There is no thought without phosphorus), may warrantably be altered to "Ohne phosphor gar kein Leben"—(There is no life without phosphorus). If this conclusion can be correct, it follows that the solutions before you which have developed fungi contained phosphorus in some form or other, which has admitted of the growth of the fungi, and since boiling was the only difference (in nearly all cases) in the treatment of the solutions, the boiled solutions must contain it as well. If this be so, we arrive at a conclusion which is again in favour of the Biogenesis theory; this is, that since the conditions essential to life are complied with by the solutions, and yet no life is developed, the living matter present in the solutions before being boiled has its life destroyed by the ebullition.

16. Moreover, these solutions become the means whereby to test the truth or falsity of Professor Frankland's

conclusion, and I intend, in a few days, to put it to the test of experiment (see Appendix). In order that you may understand the plan on which I intend to proceed, it will be necessary for me first to lay before you, as briefly as possible, the mode of experiment followed by Professor Frankland. He took a quantity of water as supplied to the metropolis for domestic purposes, and added to it a quantity of sugar; the water was then allowed to stand for a week or ten days to see if fungi developed, if not the absence of phosphorus was shown, and, consequently, it was necessary to add it to the water in some form or other, in order that these low forms of life might grow in the weak sugar solutions. He thus found that phosphorus in some form was essential to the development of these fungi, and from this he concludes that it is essential to life. You will now be prepared for the plan which I have devised as the *experimentum crucis* on this point. I have here two pint stoppered bottles filled with Middlesbrough water; to the water in the one marked A, 5 grammes of pounded loaf-sugar were added, when drawn, on the 18th of February; to the one marked B, the same quantity of sugar was added, and 5 grms. of tartaric acid in addition—both solutions were then allowed to stand. If neither of them developes fungi, the conclusion must follow that neither of them contains phosphorus: if only B does, it will show that the tartaric acid added contains it, while, if both do, it will show that both contain it (though the quantity of fungi developed will probably show which contains most phosphorus), and will not necessarily indicate (unless, as has just been said, the quantity is greater), that the tartaric acid added does. If the last result is obtained, the experiment will have to be repeated with water free from phosphorus in order to obtain reliable results. As yet, as you see, no fungi have made their appearance. When the experiment is successful I shall have pleasure in laying the result before you (see Appendix).

17. I cannot sit down with remarking on the benefit I have derived from this course of experiments. I commenced them little thinking of the extent of bearing they would have on such important questions as those of the origin of, and conditions essential to, life; and, to my mind, it is only one more in the host of researches which, commenced in obscurity, and also having bearings apparently obscure, have eventually thrown light upon questions of the greatest moment. This of itself is a sufficient reward for the labour these experiments have entailed, and will stimulate me to further research on this and other kindred subjects (as well as others), to the end that truth may be increased; and in this search for scientific truth, I trust I shall not be alone in the host of members of the Cleveland Literary and Philosophical Society who are interested in science.

Appendix.

I.—Solutions referred to.—Particulars received from Halifax, March 20th, 1871.

Solution C. of August 12th, 1868.—Not mouldy. Liquid quite clear.

Solution No. 2, of September 21st, 1868.—Not mouldy. Solution clear and sparkling; bright particles float about when shaken.

II.—Results of experiments made February 18th, 1871, to determine whether tartaric acid contains phosphorus or not.

A. has developed a quantity of filmy brownish-white fungi. The solution is clear.

B. has developed a larger quantity of fungi, of a similar colour, but the form is somewhat globular. The solution is turbid.

From these results I conclude that the tartaric acid added either contained phosphorus or more living matter, which developed in a weak sugar solution. A further experiment with boiled solution of the acid will be necessary, in order to show which of the two conclusions is the correct one.

ON THE
DETERMINATION OF NITROUS ACID,
WITH SPECIAL REFERENCE TO THE
MANUFACTURE OF OIL OF VITRIOL.*

(Concluded from p. 239).

By W. CROWDER.

THE annexed tables are the result of a series of experiments in illustration:—

1st. Of the constancy of results obtained by the processes adopted.

2nd. A series of analyses of samples of nitrous and denitrated vitriol from four different works, illustrating the three different methods of denitrating, viz.:—

1st. By steam alone.

2nd. By a mixture of steam and sulphurous acid.

3rd. By passing nitrous vitriol down a column, and denitrating it by the hot sulphurous acid as it comes from the burners, which also concentrates the acid at the same time.

ANALYSIS OF VARIOUS SAMPLES OF NITROUS VITRIOL BY THE UREA AND PERMANGANATE PROCESSES, OBTAINED FROM FOUR ACID WORKS ON THE TYNE.

First Works—Acid Denitrated by Steam alone.

	Sp. gr.	By the urea process.	By the permanganate process.

NOTES OF

DEMONSTRATIONS ON PHYSIOLOGICAL
CHEMISTRY AT ST. GEORGE'S HOSPITAL.

By S. W. MOORE.

IV.

It will be convenient to pass over active principles and colouring matters, &c., considering them as they occur in their respective tissues and fluids. Non-nitrogenous matters will occupy our attention, as sugars, fats, &c.

Sugars Occurring in Animal Tissues.—Lactose in milk, glucose in urine, inosin in muscles, and glycocine, not as such, but as hippuric acid, which, as mentioned previously, is glycocine with an atom of H displaced by the radical benzoyl.

Lactose, or sugar of milk ($C_{12}H_{22}O_{12}$), is found exclusively in milk; it is secreted in the largest quantities by Herbivora, but also by animals fed exclusively on meat; it is a hard gritty body, crystallising in four-sided prisms, terminating in four-sided pyramids; sparingly soluble in cold water (5 parts), thus accounting for its inferior sweetening property; it turns a ray of polarised light to the right, is not fermentable, may be converted to galactose by boiling with acids; this is a fermentable variety, reduces copper salts in an alkaline solution, and combines with bases to form definite compounds. Lactose may be prepared by removing the casein from milk and evaporating the whey until crystals form.

Cow's milk contains 4 per cent, human milk 7 per cent of lactose; thus a few grains of lactose added to cow's milk approximates its composition to that of human milk.

Glucose, or grape sugar ($C_6H_{12}O_6 \cdot H_2O$), occurs in the urine of diabetic patients as dextrose; its sweetening power is not so great as that of cane sugar; the variety from urine does not crystallise; it is dissolved but sparingly by alcohol; H_2SO_4 converts it to sulphosaccharic acid; KHO converts it to melassic acid; copper salts in alkaline solutions when boiled are reduced by glucose; it is also readily fermentable. A saturated solution of NaCl mixed with a solution of glucose crystallises in cubes ($NaCl \cdot H_2O \cdot 2C_6H_{12}O_6$).

The frequent occurrence of sugar in the urine has led to the use of various tests, some of which are anything but reliable.

Runge's Test.—A film of the suspected fluid is evaporated to dryness on a porcelain dish and H_2SO_4 added; if sugar be present it is charred by the acid. It is asserted that albumen gives the same result; this is true to a certain extent, the charring is not so definite.

Trommer's Test.—This consists in adding to a portion of suspected fluid an equal bulk of *liq. potassæ*, and a few drops of solution of $CuSO_4$; the hydrated oxide of copper is thrown down; this is reduced to the suboxide, Cu_2O , on boiling if sugar be present.

Fehling's or Barreswill's Test.—This is a modification of the above, the potassic-cupric-tartrate being used instead of the $KHO + CuSO_4$.

The Copper Test serves not only as a qualitative but as a quantitative test for sugar; thus, if you have a volumetric solution of copper salt, made as directed in Mr. Sutton's "Volumetric Analysis," the estimation of the amount of sugar is readily made. A measured quantity of urine known to contain sugar is taken and heated in a porcelain dish; into this while boiling the copper solution is slowly discharged from a burette properly graduated; as soon as the urine becomes blue, the whole of the sugar has been expended in reducing the copper salt. The number of divisions of the volumetric solution used represents the amount of sugar in the known quantity of urine; this multiplied by the total quantity excreted in twenty-four hours gives the amount of sugar passed in that time.

Fermentation Test.—This perhaps is the best test of quantity, as it is most readily performed. Into a tube filled with mercury and inverted in a vessel full of the same metal is passed a measured quantity of saccharine urine, and with it a small piece of yeast; the whole thing is then left for twelve hours; at the end of that time the sugar will have been converted into CO_2 and H_2O ; the first being a gas ascends and displaces the mercury. Every cubic inch of CO_2 thus formed represents about 1 grain of sugar, or more exactly 100 cubic inches represent 106.6 grains of sugar; the same rule as before gives the quantity passed in twenty-four hours.

The growth of *Torula*, a species of conservoid vegeta-

tion, is said to be characteristic of the presence of sugar. The presence of sugar in the blood has not been satisfactorily accounted for.

Inosin, or muscle sugar, is not of sufficient import to demand attention; of glycocine we have already spoken.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 16th, 1871.

Professor ODLING, F.R.S., Vice-President, in the Chair.

AFTER the minutes of the previous meeting had been read and confirmed, and the donations to the Society announced, the names of the following gentlemen were read for the first time:—Christopher Childs, William W. Abney, Jonathan Ingle Calvert, and Frederick J. Montague Page.

For the second time—William Gray, Frederick Hicks, Robert Irvine, Samuel William Moore, Donald Munroe, Hugh Paterson, Benjamin Tanner, Charles Thomas, William John Wilson, George Joseph Warner, and Reginald C. Woodcock.

The SECRETARY then read a paper "*On Burnt Iron and Steel*," by W. H. JOHNSON, B.Sc. In it the author expresses his opinion that the burning of iron and steel is not due to the action of uncombined oxygen. It would appear Mr. Williams thinks this to be the case from his paper, an abstract of which appeared in the *Journal of the Chemical Society*, but the oxygen does not exist in a free state in the hottest part of the furnace, as it is there united with carbon, forming carbonic acid and carbonic oxide. After referring to Mr. Lowthian Bell's experiments on the oxidising effect of carbonic acid, and the reducing action of carbonic oxide on iron at different temperatures, the author draws attention to the fact, that immediately the oxidising effect of the carbonic acid present becomes greater than the opposite action of the carbonic oxide, the iron begins to burn. The relative proportion of the two gases at which the point of equilibrium occurs varies greatly with the temperature; the higher this is, the smaller is the proportion of carbonic acid in the mixed gases necessary to produce the injurious effect; it takes place, moreover, with greater readiness when a comparatively pure iron is employed than with one containing sulphur or silicon. As red-hot iron is permeable to carbonic acid and carbonic oxide, their action is not confined merely to the surface, but penetrates into its substance. This induces the author to believe that the well-known increase of bulk which takes place when iron is repeatedly heated, is due to the formation of an oxide in the body of the metal, thereby increasing both its volume and its weight.

Dr. ODLING said that, although the Society but seldom received papers of an argumentative character, the thanks of the members were due to the author for his observations on this important subject. The relation between the burning of iron and steel, and the experiments of Mr. Lowthian Bell on the varying oxidising power of carbonic acid at different temperatures and the corresponding reducing action of carbonic oxide, was of great interest, showing that there was a point at which these actions going on at the same time, so to speak, neutralised one another.

Mr. E. RILEY said that it was quite as important to consider the mechanical treatment to which iron was subjected as the chemical reactions which took place; for instance, when iron which is so brittle as to be quite useless is piled two or three times it acquires, to a greater or less degree, a fibrous texture, whilst the very best iron, when melted in a crucible, yields a button which works very well under the hammer, but is otherwise quite changed, having become red-short. Great misconception

also existed as to the injurious action of many substances usually supposed to be prejudicial to the good quality of iron and steel. Iron containing silicon, for example, was difficult to puddle, but in steel its presence in small quantity was decidedly advantageous.

Dr. ODLING asked whether he included phosphorus and sulphur amongst these substances.

Mr. RILEY replied that the presence of phosphorus was certainly beneficial in some cases; Swedish iron puddled, is red-short, but when mixed with the proper proportion of Cleveland iron containing phosphorus, it yields an excellent iron. Lowmoor iron and the Yorkshire pig made from clay ironstone usually contain about 0.64 per cent of phosphorus, and the amount seemed to be the same whether the hot or cold blast were employed. Steel containing 0.1 per cent of phosphorus was bad, but he did not agree with those who say that the presence of silicon in steel is injurious. Silicon is necessary in the Bessemer process, and the best pig-iron sometimes contains a considerable quantity of it, the speaker having in his possession a piece of very superior quality which has as much as 2 per cent. Tungsten also may exist in very large proportion in steel; he had a specimen of very hard and most excellent steel which contained more than 10 per cent of it.

Dr. MULLER asked whether the so-called Mushet's "titanium steel" contained titanium, as he had been unable to detect any in a sample he had examined.

Mr. RILEY said that he had never found titanium in any white iron, and believed that it occurred only in grey iron.

Mr. F. W. HART then described an improved syphon, consisting of an ordinary syphon having a globe at the bend furnished with a short vertical tube. The latter serves the purpose of starting the syphon, whilst the globe retains any gas that might be given off from the liquid, and which in an ordinary syphon would fill the bend and stop its action. A filter, consisting of an inverted funnel furnished with a perforated disk and covered with a layer of cotton wool or other suitable material can be attached to the shorter leg of the syphon.

Professor McLEOD observed that the instrument was not new to him, as he had seen one of very similar construction in use some five or six years ago in the laboratory of the Royal Institution.

Mr. HART stated that it was now about five years since he had first made one of these syphons, and, as far as he had been able to ascertain, no account of it had yet been published.

Dr. VERNON HARCOURT said that he had had a syphon in use for a considerable time precisely similar to the one described. It is employed to maintain a constant level in the still of a distilled water apparatus, by supplying it with warm water from the worm tub of the condenser.

The CHAIRMAN then announced the adjournment of the meeting until Thursday, December 7, when a paper would be read by Dr. GLADSTONE "On Essential Oils."

GLASGOW PHILOSOPHICAL SOCIETY. (CHEMICAL SECTION).

THE business of the Section was resumed on the evening of Monday, the 6th inst., when Dr. W. Wallace, F.R.S.E., F.C.S., the President, delivered the opening address, which was occupied with a brief notice of certain topics of local interest, including the arrangements in the chemical department of the new buildings of the University of Glasgow, the appointment of Prof. Gustav Bischof to the Young Chair of Technical Chemistry in Anderson's University, the statue of the late Master of the Mint to be erected in Glasgow at the expense of Mr. James Young, and the disposal of the sewage, especially referring to Mr. Stanford's system of using seaweed charcoal as a deodorant of human excreta, and Mr. Gavin Chapman's method of utilising the urine from the public urinals of Glasgow.

Dr. Wallace also referred to the raid which parochial Boards in Scotland are making at the instigation of the Board of supervision in Edinburgh against the well-waters that are found to contain sewage contaminations. His large experience in analysing the waters of towns and villages justified him in saying that at least two-thirds of such waters are unfit for domestic use. In connection with this subject, he took notice of the evidence given by Dr. Letheby on the Edinburgh Water Bill last session, particularly in respect of the unhealthy character of soft waters, such as those supplied to Glasgow, Manchester, and other large towns where the mortality rates are high, and quoted from Mr. Bateman some remarks as a sort of reply to Dr. Letheby. Dr. Wallace considered that the more scientific physicians were the only persons who were competent to express opinions upon the subject, and he hoped they would inquire into it. Of the recent improvements in the alkali trade, Dr. Wallace spoke of and enlarged upon Weldon's process for regenerating manganese, Deacon's chlorine process, and Hargreaves's process for decomposing common salt by sulphurous acid. In metallurgical chemistry he referred to the difficulty and expense of making spiegeleisen for the Bessemer steel process, expressing his belief that ere long a suitable iron ore for this alloy would be got in Ireland in large quantity; to the splendid manganese colours obtained by Mr. Rowan, a member of the section; to Mr. Ferrie's self-coking blast-furnace; and to the introduction of the manufacture of zinc into Scotland. Mr. Spence's process of treating mineral phosphates in the manufacture of artificial manures was noticed, and so likewise were various topics connected with the subject of artificial lighting, and one or two others. The address was in every sense a most comprehensive and interesting one.

November 20th, 1871.

The annual meeting of the same section was held this evening, Dr. Wallace, the President, in the chair. After the transactions of some formal business, the election of the office-bearers of the section was proceeded with. As re-constituted the council consists of:—

President—Dr. William Wallace, F.R.S.E., F.C.S.

Vice-Presidents—Messrs. John Ferguson, M.A.; John Jex Long; W. R. Hutton.

Treasurer—Mr. P. M. Moir.

Secretary—Mr. R. R. Tatlock, F.R.S.E., F.C.S.

Other Members of Council—Dr. John Clark; Messrs. James Anderson; J. Couper; John Sutherland; James Macfear, F.C.S.; T. L. Paterson, F.C.S.; Alexander Whitelaw.

Before the meeting separated the President announced that a number of important papers had been promised for the ensuing session from Dr. Clark, Dr. T. E. Thorpe, Professor Bischof, and other members and associates of the section.

CORRESPONDENCE.

RELATION OF HEAT TO ELECTRICITY.

To the Editor of the Chemical News.

SIR,—It is generally said that the heat produced by a current of electricity varies as the square of the current (with the same resistance). I have no doubt that this is true in the cases from which the rule has been deduced, namely, where the sources of the electricity have been the same.

The following experiment would tend to throw a doubt on the general truth of the rule where the electricity is derived from different sources:—

I took two elements, one of zinc-platinum, and the other of iron-carbon, with the same electrolyte. The current from the former was 87° on a tangent galvanometer, of the latter 85°; consequently, the heating effects of the two currents ought to have been as the squares of the tangents of those angles, or about as 36 to 13; yet, on trial, I found the former would keep only about 1½ inches of a platinum wire red-hot, whilst the latter would keep 2½ inches of the same wire red; also in deflagrating different gauges of iron wire, I found that the latter would deflagrate like tow wire, which the former would keep scarcely red-hot. The sparks from the latter were also much more brilliant than from the former, emitting bright flashes and scintillations when a copper wire was rubbed along the rough edge of a rusty piece of iron.

The subject is worth investigation, and I venture, through your columns, to call the attention of scientific men to the point.—I am, &c.,

H. HIGHTON.

2, The Cedars, Putney,
Nov. 18, 1871.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 30, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Thermal Researches on the Electrolysis of the Alkaline Bases and Alkaline Sulphates.—P. A. Favre.—The continuation of a very lengthy and exhaustive memoir on this subject.

Idocrase from Arendal in Norway.—A. Damour.—The sp. gr. of this mineral = 3.44; it is harder than felspar, fuses by the action of the blowpipe flame, is readily acted upon by acids, and consists, in 100 parts, of:—Silica, 36.32; alumina, 16.70; lime, 34.86; protoxide of iron, 0.6; protoxide of manganese, 0.14; magnesia, 0.07; water, 0.25. Formula, $18(\text{CaO}, \text{FeO}, \text{MnO}, \text{MgO}) + 4\text{Al}_2\text{O}_3 + 15\text{SiO}_2$.

Analysis of a Mexican Grenate.—A. Damour.—The specimen alluded to was obtained from a locality, Rancho de San-Juan, where a crystalline limestone is the prevailing rock. The sample was crystalline; colour, pale rose-red; hardness, greater than quartz; sp. gr. = 3.57; readily fusible before the blowpipe flame, forming a semi-transparent yellow-brownish glass. When fused in the reduction-flame along with borax, the mineral yields a colourless glass. The grenate is slowly acted upon by acids, but readily dissolved by these, after having been first ignited to redness in a platinum crucible. Composition, in 100 parts:—Silica, 39.46; alumina, 27.69; peroxide of iron, 1.36; lime, 35.75; magnesia, 0.67; protoxide of manganese, 0.96; volatile matter, 0.4.

Note on the Use of Dynamite.—M. Barbe.—The contents of this paper may be summarised by stating that the author has given a very complete review of the various uses to which dynamite may be applied, while setting forth the great superiority of this explosive material over gunpowder, also as regards greater safety against accident. It appears that dynamite is manufactured in France in very large quantities, and is also rendered applicable for military artillery purposes.

Conversion of Cane Sugar in the State of Solution into Glucose under the Influence of Light.—E. M. Raoult.—The author placed, on May 10 last, a concentrated solution of sugar in water in glass tubes, and, while boiling the same, sealed the tubes; these were placed close to each other in the same locality and under identically the same conditions, with the exception that one of the tubes was kept completely in the dark, the other tube being exposed to bright daylight. On October 20 last the tubes were opened, and the contents examined. The solutions were perfectly clear, and did not, on being microscopically examined, exhibit the least trace of vegetable matter. The fluid in the tube exposed to light yielded an abundant red-coloured precipitate with the cupro-potassic reagent, thereby indicating the presence of glucose, while the contents of the tube kept in complete darkness did not manifest that reaction at all.

Continuation of the Thermo-Chemical Researches on Ammoniacal Salts.—Dr. Berthelot.

Spectra of Phosphorus and of Silicon Compounds.—G. Sallet.

November 6, 1871.

This number contains the following original memoirs and papers relating to chemistry and collateral sciences:—

Mode of the Repartition of Potassa and Soda in Plants.—E. Peligot.—The fourth portion of a very lengthy and exhaustive chemico-agricultural essay; this part treats on the influence of common salt as occurring more particularly in soils of drained fen-lands and land recovered from the sea.

Thermal Researches on Electrolysis.—P. A. Favre.—The continuation and end of the very exhaustive memoir on this subject.

Observations on the Solubility of Chloride of Silver in Reference to the Recent Communication of M. Staa.—I. Pierre.—The author quotes some observations made by him, as far back as the year 1844, on the solubility of chloride of silver in strong hydrochloric acid, and the precipitation of the chloride by the subsequent addition of water, and also calls attention to the fact that boiling nitric acid may dissolve, and convert into nitrate of silver, the chloride alluded to.

Formation of Precipitates.—Dr. Berthelot.—A thermo-chemical essay divided into the following sections:—Formation of a solid compound; dehydration of precipitated compounds, lime, carbonate of lime, carbonate of magnesia, carbonates of iron and manganese, sulphates of lime, baryta, and strontia.

Detection of Hydrochloric Acid in Cases of Poisoning with that Acid.—J. Bouis.—After referring to the difficulty of detecting whether small quantities of the acid alluded to—always present, though in very minute quantity only, in the natural and healthy stomachic juices—are due to a poisonous dose, the author advises that the contents of the stomach to be tested should be first filtered through paper or fine muslin previously moistened with acetic acid, and that to the filtered liquid gold-leaf be added, and a few grains of chlorate of potassa. The mixture is then heated on a water-bath, and tested afterwards with protochloride of tin, to see whether any gold is dissolved; the substances to be tested should, however, first be tried for the presence of free nitric and sulphuric acids.

Journal de Pharmacie et de Chimie, September, 1871.

This number contains the following original papers and memoirs:—

Researches on the Action of the Substances which Aid the Decomposition of Chlorate of Potassa while Employed for the Preparation of Oxygen.—Dr. E. Baudrimont.—The continuation and end of this lengthy memoir. This portion contains the following sections:—Influence of the nature of the bodies present with the chlorate of potassa—the bodies experimented with are:—Spongy platinum, red oxide of mercury, oxide of silver, permanganate of potassa, black oxide of copper prepared by the moist way, native peroxide of manganese, peroxide of iron, protosulphate of manganese, black oxide of cobalt, peroxide of lead, oxide of aluminium; influence of the state of division of these substances; influence of the temperature; study on the chemical action which certain substances exert upon chlorate of potassa; on the action of contact; on the origin of the chlorine with which the oxygen is contaminated; is the oxygen evolved from chlorate of potassa in the state of ozone? observations on the fusion of chlorate of potassa when an active substance has been added thereto.

Differences which the Divers Processes for the Estimation of Cream of Tartar Exhibit.—P. Carles.—The contents of this paper record a few experiments made by the author with the view to prove that the estimation of cream of tartar (bitartrate of potassa) in wines, when the salt alluded to is precipitated from that liquid by the aid of a mixture of alcohol and ether, may, as compared with the method of calcination (after evaporating the wine to dryness, and calculating the weight of the carbonate of potassa obtained as representing bitartrate of that base), lead to great differences of result, due to the presence in some kinds of wine of other organic potassa salts which are not precipitated by a mixture of alcohol and ether. The contents of this paper are of particular value to wine-growers; that the difference alluded to is not small may be inferred, for instance, from the fact, that in a sample of Malaga wine, the precipitation process only yielded 0.95 and the calcination process 3.40 parts per litre of bitartrate of potassa, a quantity too large to be held in solution in the wine as an alcohol-containing liquid.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, September, 1871.

The following original papers are contained in this number:—

Antidotes to Poisoning with Carbolic Acid.—Dr. T. Husemann.—An interesting chemico-therapeutical essay, in which the author recommends, upon sound practical and experimentally-proved grounds, the use of a strong solution of saccharate of lime as an antidote against poisoning with carbolic acid, when by accident taken internally.

Practical Observations on Essential Oil of Mustard Seed.—Dr. F. A. Flüchiger.—The contents of this essay may be summarised as follows:—When to the essential oil of mustard seed 3 parts of concentrated sulphuric acid are slowly and gradually added, care being taken to cool the mixture, sulphurous acid and sulphocarboxylic oxide are evolved after twelve hours' standing. The mixture should either be clear yet very thick, or entirely converted into a crystalline mass; the mixture should then exhibit no longer the peculiar odour of oil of mustard seed, but, in addition to a slight smell of sulphurous acid, that of leek. The colour of the mixture should not be turned dark; when a parts of the essential oil

are mixed with 1 of absolute alcohol and from 6 to 8 of strong liquid ammonia, and heated to 50° for some time, the result should be that, on cooling in open shallow vessels, the mass becomes crystalline (formation of thiosiammin); the mother-liquor from these crystals should leave, by spontaneous evaporation, crystals, but hardly any fluid, which should scarcely, moreover, exhibit the smell of leek. These reactions, along with the specific gravity, characterise mustard seed oil very distinctly.

Les Mondes, November 9, 1871.

Telegraphic Rockets.—M. Papafy.—The author has devised a series of sky-rockets (fireworks) adapted for telegraphic service at night for armies when in the field, so arranged that each rocket is, by a variation of coloured light, capable of transmitting six words, visible at a distance of 32 kilometers = 19,872 English miles. These signals can be readily kept unintelligible to the enemy, while everything relating to military and strategical matters can be easily expressed. The Prussian War-Department has bought the secret of this invention from the author, a Hungarian in service as captain in the United States Army.

New Method of Stopping in a Very Short Space of Time an Express Railway Train.—Rev. Thifion.—Illustrated by woodcuts. The contents of this paper decidedly deserve the serious attention of railway-engineers and locomotive-engine builders.

November 16, 1871.

New Hydraulic Invention.—A. Joly.—The author has invented a simple mechanism (not further specified) by the aid of which the concussion (*coup de bélier*) caused in water-conducting pipes by the sudden opening and closing of taps fitted to them, as well as the freezing of that liquid in the pipes, may be prevented.

Anhydrous and Hydrated Salts.—M. Favre.—All the crystallised anhydrous salts generate on being dissolved in water, cold, while the crystallised hydrated salts cause the evolution of heat, when becoming dissolved in water.

Chemical Laboratory at Neuchâtel (Switzerland).—Dr. Sacc.—From a short abstract, taken from the Report of the Cantonal Inspector of Public Instruction, here published, we learn that this laboratory, the property of the caaton which bears the name of its chief town (above quoted), is every year becoming of greater importance. The collections of samples and specimens, minerals, ores, organic and inorganic compounds, instruments, and library, are almost daily added to either by the kind attention of donors interested in science, arts, and industry, or by purchase, and last, but not least, by the preparations made by the students who work there, their number being at present about ninety; most of these are foreigners to the Republic, the Government of which may be highly congratulated on the very favourable results its care has produced, as regards providing sound, effective, and cheap public instruction not only in respect of the high intellectual development of the inhabitants, but also of a very large number of foreigners. The regulations at Neuchâtel as regards those who desire to learn chemistry, both practical and theoretical, are such that the instruction may be said to be almost gratuitous.

Sitzungsberichte der Mathematisch-Physikalischen Classe der Königlich Bayerischen Akademie der Wissenschaften zu München, vol. i., 1871.

The original papers and memoirs relating to chemistry published in this volume are the following:—

Metamorphosis of Matter Observed in Casca of Poisoning with Phosphorus.—Dr. J. Bauer.—The contents of this lengthy memoir dwell on the peculiar effect of phosphorus, which results in an elimination of nitrogenous matters from the bodies of men and animals to whom large doses of this element are given, and the production of an excess of fat, due to an imperfect process of oxidation.

Geognostic Relation of the Ulm Cement Marl and its Affinity to Lithographic Stone, and the Foraminifera-Fauna which Accompany the Latter.—Dr. Gümbel.—This essay, accompanied by several engravings, treats on a peculiar kind of mineral met with near Ulm (Württemberg), and used for the purpose of preparing hydraulic cement. The contents of this paper are strictly geognostical and palæontological.

Realisation of Certain Kinds of Ash-Constituents of the Animal Body.—Dr. Voit.—A physiologico-chemical essay on nutrition and on the action of certain inorganic constituents of the animal body in its embryonic state.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
November 9, 1871.

Newly-Invented Ozone-Generating Apparatus.—M. Ruhmkorff.—The detailed description, elucidated by a woodcut, of a contrivance by the aid of which, under the influence of a very large number of electric sparks, air may be ozonised in a closed space, and the ozone so formed applied for use in chemical operations.

Apparatus for Measuring the Intensity of the Sun's Radiation.—Rev. Father Secchi, S.J.—This description is also illustrated by a woodcut.

Composition of Calorific Value of Two Samples of Welsh Coal.—M. Scheyer-Kestner and C. Meunier.—The coals alluded to are

Bwlfl and Powell.—The former consists, in 100 parts, of:—Water, 0.63; carbon, 87.48; hydrogen, 3.68; ash, 3.32; oxygen, 4.89; yields 82.08 per cent of a slightly caked coke; 1 kilo. of this coal evaporates 8.826 litres of water; calorific value = 8,780. The latter-named coal consists, in 100 parts, of:—Water, 0.75; carbon, 88.36; hydrogen, 3.80; ash, 3.72; oxygen, 3.31; yields 81.16 per cent of coke; 1 kilo. evaporates 9.076 litres of water; calorific value = 8,949. The authors, having been engaged for a considerable length of time in making researches on mineral fuel, have found that, as regards coal, the heat it yields by combustion exceeds that of the heat of all its constituent elements (when completely burnt) added together, while, as far as lignite is concerned, it appears that just the reverse obtains.

Continuation of the Tabulated Review of the Composition of Fertilising Substances which may be Added to Manures or are fit for Use as such by themselves.—C. Mène.—(See *CHEMICAL NEWS*, vol. xxiv., p. 182).

Bibliography.—Under this heading we find here short reviews of the two following books, lately published by MM. Hachette, viz.:—"Nôtre Planète," par M. J. Duval. This work treats more particularly on the relation existing between political economy and geography, and dwells at some length on anthropology as viewed in reference to recent discoveries. "Éléments de Zoologie," par Dr. P. Gervais. The second and greatly enlarged and improved edition of a work edited by one of the most competent scientific authorities on this subject in Europe. For clearness of views, and sound inductive treatment of the subject, this work deserves the attention of all who desire to obtain some knowledge in zoology.

La Revue des Scientifique de la France et de l'Etranger,
Octobre 28, 1871.

This number does not contain any original papers on chemistry, but we call attention to the excellent lecture:—

Phænomena of Respiration.—Dr. Gréhaut.—The continuation of this subject, illustrated by several woodcuts, and treating on the respiration of fishes, extraction of gas from blood, and on hemoglobin.

NOTES AND QUERIES.

Specific Gravity.—Would any of your readers kindly inform me of a method of finding the specific gravity of any liquid by Twaddle's hydrometer, from the lowest to the highest indications, and oblige a tyro.—J. W.

Refining and Bleaching Tallow.—Can any of your readers oblige me with the best and cheapest mode of refining and bleaching tallow for manufacturing purposes? A good colour is wanted.—B.S.O.

Gallie Acid.—Thanks to Hugo Tamm, but he has missed the purport of the enquiry; nor is it at all clear that "the two Hugo's agree splendidly together." If in conforming to a wide formula of genesis, tannic acid is a di-gallie acid, and tannin is a tri-gallie glucide; then it is next to certain that the radical of gallie acid is $(C_7H_5O_4)$, and such, I believe, it will be found in any future amonomical sulphonic acid, or other substitutional derivative. Will "H. T." favour the enquirer with his address.—S. E. P.

Law of Compound Proportion.—In the *CHEMICAL NEWS* some time ago, I think I read a note saying, "That the law which used to be called 'compound proportion' was not correct." Rather, the words took this form, "That the formula of a compound body cannot be called the 'equivalent' of that body." And it gave an example, naming a salt, and saying that the sum of its components were not the equivalent of that body capable of combining with any other named. Now, is this true, or how far is it true, that the equivalent of a compound is the sum of its components, i.e., the sum of the equivalent of its components?—E. K.

Weighing Deliquescent Substances.—I do not know if I suggest a new detail, but, taking the benefit of the doubt, I wish to mention the following:—Having been repeatedly aggravated by the conduct of deliquescent substances in the balance, I selected a light beaker, and a bit of ground glass to cover it, and, grinding the edge of the beaker, which just admits the crucible, I find that I can weigh with all desirable deliberation, crucible, lid, beaker, and cover. I keep all in the desiccator, and of course know their weights. It is a great relief to my mind not to risk the accuracy of my weighing for the sake of speed.—MARSHALL HALL.

MEETINGS FOR THE WEEK.

MONDAY, Nov. 27th.—London Institution, 4. Prof. Huxley, LL.D., F.R.S., on "Smell, Taste, and Touch" (Course of Elementary Physiology).

Medical, 8.
Royal Geographical, 8.30.

TUESDAY, 28th.—Civil Engineers, 8.

WEDNESDAY, 29th.—Society of Arts, 8.

THURSDAY, 30th.—London Institution, 7.30. Mr. P. L. Simmonds, F.R.C.I., F.S.S., on "Science and Commerce Illustrated by the Raw Materials of our Manufactures (II.)."

Royal, 4. Anniversary.

TO CORRESPONDENTS.

A Subscriber.—A book on the subject is in the press.
L. S. L.—Consult the *Proceedings of the Royal Society*.
M.—The best material you can use for greasing stoppers of bottles containing caustic and carbonated alkalies, is raw unrefined paraffin which is still contaminated with tarry matter. The stopper and neck of the bottle should be wiped dry and well ground.
C. R. S.—A work will shortly be announced which will meet your requirements.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

THE CHEMICAL NEWS.

Terms of Subscription, Post Free.

The *CHEMICAL NEWS*, will be regularly forwarded direct from the Office to any address within the United Kingdom at the following rates:—

Quarter	£0	5	0
Half-Year	0	10	0
Year	1	0	0

Terms for Advertisements.

One Page	£3	0	0
One Column	1	15	0
Half-Column	1	0	0
Five Lines and under	0	3	6

Contracts made for repeated insertions.

Post Office Orders to be made payable to HENRY GILMAN, at the Chief Office.

BOY COURT, LUDGATE HILL, LONDON, E.C.

Now ready, price 4s., with coloured frontispiece of the more important of the Spectra.

Inorganic Chemistry, by the late Professor

GEORGE WILSON, of Edinburgh University; thoroughly revised and brought up to the latest state of the Science by H. G. MADAN, M.A., Fellow of Queen's College, Oxford, and Natural Science Master in Eton College.

W. and R. Chambers, London and Edinburgh.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

New Laboratory Apparatus:—

CENTRE BLAST BUNSEN, combining a Bunsen, and a very powerful Herapath, 30s. 6d.

HOT-BLAST BLOWPIPE, giving the temperature exceeding the fusing-point of platinum, 9s. 6d.

TABLE FURNACE, without blast, for operations below a white heat, 30s.

The above were awarded the first medal of the Royal Cornwall Polytechnic Society, 1871. Drawings, &c., one stamp.

T. FLETCHER, 35, BOLD ST., WARRINGTON.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA OF HONOUR, being the First Prize, and superior to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867. TWO GOLD MEDALS; HAVRE EXHIBITION, 1868. THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2½d., which costs 1s. if made fresh from meat. Cheapest and finest flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar sold by all Italian Warehousemen, Grocers, Chemists, and Ships. Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, and clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian, and other Governments.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock, on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c.: of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

North London School of Chemistry, Pharmacy, &c.

For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871-1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fees to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

ANALYTICAL LABORATORY AND SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufacture, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied and the Erection of Plant and Buildings is superintended when required.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEYS, Ardwick Chemical Works, Manchester.

THE CHEMICAL NEWS.

VOL. XXIV. No. 527.

CONTRIBUTIONS TO THE HISTORY OF THE OPIUM ALKALOIDS.*

By C. R. A. WRIGHT, D.Sc.,

Lecturer on Chemistry in St. Mary's Hospital Medical School.

PART III.

1. Action of Hydriodic Acid on Codeia in Presence of Phosphorus.

IN Parts I. and II. of these researches the action of hydrobromic acid on codeia and its derivatives has been partially investigated; and as the action of this acid appears to be in some respects similar to, but in others different from that of hydrochloric acid, it appeared to be of interest to examine the action of hydriodic acid also.

Some preliminary experiments on this subject made two or three years ago in conjunction with the late Dr. A. Matthiessen, showed that when codeia is boiled with a large excess of strong hydriodic acid, no appreciable quantity of methyl iodide is evolved even after some hours' treatment; a brown tarry mass containing much free iodine was produced, but at the time nothing fit for analysis was obtained from this; since then, Dr. Matthiessen and Mr. Burnsides† have corroborated the non-formation of methyl iodide under these circumstances.

If, however, phosphorus be added simultaneously with the hydriodic acid, so as to prevent the accumulation of free iodine, methyl iodide is evolved at 100° and upwards in quantity close upon that required for the equation—

hitherto, however, no body of this latter formula has been isolated from the products of the reaction, the substances ultimately formed being derived from a base containing H₂ more than morphia.

The hydriodic acid was obtained in the first instance by the action of hydric sulphide on iodine and water; in the dilute acid thus got iodine was dissolved, and the whole digested at a very gentle heat with phosphorus, more iodine solution being added from time to time; finally the whole was distilled several times from potassium iodide. A colourless acid of sp. gr. 1.7 to 1.75, and containing 50 to 55 per cent of HI was thus obtained, and preserved colourless by keeping a stick of phosphorus in the bottle. The codeia used in these experiments was part of a further supply most liberally presented by Messrs. Macfarlane, of Edinburgh.

On heating on the water-bath a mixture of 10 parts codeia, 30 to 50 of this acid, and 1 of phosphorus, the evolution of methyl iodide is noticed in a few minutes; simultaneously the liquid becomes brown, indicating the separation of free iodine; after two or three hours the brown colour disappears, and the evolution of methyl iodide ceases. If the liquid be heated to gentle ebullition, at first the same effects ensue, but more quickly; the resulting product, however, varies in composition according to the temperature at which the reaction was effected.

In one experiment 55 grms. of codeia yielded by condensation 22.5 grms. of methyl iodide, the theoretical yield being 24.6 from crystallised codeia, C₁₈H₂₁NO₃.H₂O; hence upwards of 90 per cent of the theoretical yield was obtained. In order to prove the elimination of 1.18th part of the carbon in the form of methyl iodide, 4.3045 grms. of codeia dried at 140° to 150° C., was heated to gentle ebullition with 30 grms. of 55 per cent of hydriodic acid and about 2 of phosphorus; the vapours evolved were

passed through a flask to condense aqueous vapour, and then through a combustion-tube filled with red-hot lead chromate, the CO₂ produced being absorbed in the usual way, an aspirator being attached at the far end so as to create a diminished pressure throughout the apparatus, and thus guard against loss of methyl iodide vapour by leakage at any of the numerous corks and joints.* After three hours a current of pure oxygen was let through the apparatus to sweep out the last traces of methyl iodide vapour from the flasks, and ensure the perfect combustion of deposited carbonaceous particles.

4.3045 grs. codeia thus gave 0.617 grm. CO₂.

0.3720 grm. codeia, burnt in the usual way, gave 0.9830 CO₂.

	Found.	Calculated.
(A) Percentage of carbon evolved as CH ₃ I } (B) Percentage of carbon in codeia used }	3.91	4.013
	72.07	72.241
Ratio of A to B . . .	$\frac{3.91}{72.07} = \frac{1}{18.4}$	$\frac{4.013}{72.241} = \frac{1}{18}$

In another experiment not carried to a complete conclusion, the CO₂ collected represented 3.7 per cent of the codeia used.

The methyl iodide produced was found, after washing with water, drying over CaCl₂, and distillation, to be free from traces of dissolved phosphorus, to boil at 42° to 45° C., and to correspond in every respect with the ordinary methyl iodide.

If the reaction with hydriodic acid takes place on the water-bath, the resulting product appears to have the composition C₆₈H₈₆I₂N₄O_{12.4}HI; but if the mixture be heated to gentle ebullition throughout, the temperature not being allowed to exceed 110° to 115° from loss of aqueous fluid by evaporation, the substance obtained contains the elements of two molecules of water less, = C₆₈H₈₂I₂N₄O_{10.4}HI; whilst if the mixture be rapidly boiled, so that by evaporation the boiling-point rises to 130° and upwards, the ultimate product contains less oxygen than this last body, being C₆₈H₈₂I₂N₄O_{6.4}HI. These three formulæ might each be halved; but inasmuch as compounds containing not less than C₆₈ have been got from these products by simple treatments, the higher formulæ are more probable.

All three substances are, while moist, colourless tars, drying at 100° to brittle waxy-looking masses, not fusing at 100° when perfectly dry; they are soluble in hot water, a decomposition being thereby produced; while moist they appear to absorb oxygen with avidity, rapidly becoming yellow or orange. They are also extremely hygroscopic, and from the high percentage of iodine contained, the ease with which they decompose on heating, and the difficultly combustible carbon left, their analysis is a matter of some considerable difficulty. From all these circumstances combined, the numbers obtained do not always accord quite as closely as might be expected in the case of crystalline and easily purified substances.

To obtain the compound C₆₈H₈₆I₂N₄O_{12.4}HI, 10 parts of codeia, 30 of 55 per cent hydriodic acid, and 1 of phosphorus may be heated on the water-bath for three to four hours, at the end of which time the evolution of methyl iodide has entirely ceased: by filtering the syrupy hot liquid through asbestos to separate particles of amorphous phosphorus and addition of a little water when cold, a colourless tar is precipitated, which soon sets to a hard brittle mass; this is broken up and thoroughly washed with water to separate the phosphorus acids produced simultaneously, and finally freed from moisture as far as possible by pressure between filter paper, and dried at 100°.

The same body may also be obtained by dissolving the original substance in slightly warm water, precipitating with sodium carbonate, and extraction of the mass thus thrown down with ether, and agitation of the first portions

* Read before the Royal Society, November 16, 1871.

† Proceedings of the Royal Society, vol. xix., p. 71.

* This device may be applied with advantage to the ordinary processes for combustion, blowing out of the tube as well as loss by traces of leakage being thus avoided.

of the ether extract with hydriodic acid: the tar thus got is identical in all respects with the original substance. After drying at 100° the following numbers were obtained:—

(A) Prepared by the first method:—

0·3785 grm. gave 0·588 CO₂ and 0·173 H₂O.
0·359 grm. gave 0·2535 AgI.

(B) Prepared by ether process:—

0·357 grm. gave 0·5655 CO₂ and 0·165 H₂O.
0·2635 grm. gave 0·1895 AgI.

(C) Another specimen prepared by ether process:—

0·316 grm. gave 0·493 CO₂ and 0·135 H₂O.
0·2865 grm. gave 0·2025 AgI.

	Calculated.		Found.			Mean.

C₆₈H₈₆I₂N₄O₁₂·4HI.

The falling short in the percentage of iodine found in these specimens is readily accounted for by the action of the water which necessarily adheres to the tarry product got by either of the above processes; it will be subsequently shown that by the action of water on this body the elements of III are removed from it.

This compound is apparently formed by the reaction—

The iodine thus set free is, of course, re-converted into HI by the action of the phosphorus, a mixture of phosphorous and phosphoric acids being thereby produced. The reaction,

$3\text{I}_2 + \text{P}_4 + 6\text{H}_2\text{O} = 2\text{H}_3\text{PO}_3 + 6\text{HI}$, requires for 50 grms. of codeia 3·45 grms. of phosphorus to be converted into phosphorous acid; whilst the equation $5\text{I}_2 + \text{P}_4 + 8\text{H}_2\text{O} = 2\text{H}_3\text{PO}_4 + 8\text{HI}$ requires 2·07 grms. to be converted into phosphoric acid. In one experiment 2·8 grms. of phosphorus, as nearly as could be estimated, were found to have become converted into the mixture of the two acids, 50 grms. of codeia having been employed.

On attempting to procure the free base C₆₈H₈₆I₂N₄O₁₂ from the hydriodate got as above, by precipitation with sodium carbonate, a snow-white mass was obtained containing, besides a small quantity of the desired base (soluble in ether), a large quantity of two other bases derived from this one (but sparingly soluble in ether). The description of the products thus got will be given in a subsequent section.

By treating codeia with hydriodic acid and phosphorus as above described, but at a temperature of gentle ebullition, not rising above 115°, a product is got on filtration through asbestos and precipitation by water containing apparently 2H₂O less than the preceding compound. Dried at 100°,

0·302 grm. gave 0·475 CO₂ and 0·135 H₂O.
0·248 grms. gave 0·1845 AgI.

C₆₈H₈₂I₂N₄O₁₀·4HI 1880 100·00

* All combustions given in this paper were made with lead chromate and oxygen; and the iodine determinations by boiling with nitric acid and silver nitrate.

Hence this substance is formed from the preceding one by the reaction—

If codeia, hydriodic acid (3 to 5 parts), and phosphorus be heated to rapid ebullition, so that most of the aqueous portion distils off along with the CH₃I formed, the boiling-point gradually rises to 130°, or a little above, at which temperature the colourless liquid begins again to become slightly brown; on precipitation of the filtered product with water &c., as before, the following numbers were obtained after drying at 100°.

Specimen A. 0·3575 grm. gave 0·589 CO₂ and 0·168 H₂O.

0·402 " 0·307 AgI.

Specimen B. 0·358 " 0·583 CO₂ and 0·164 H₂O.

0·369 " 0·2815 AgI.

Specimen C. 0·3855 " 0·635 CO₂ and 0·178 H₂O.

C₆₈H₈₂I₂N₄O₆·4HI

Hence this substance is formed from the preceding one by the reaction—

2. Action of Water on the foregoing Compounds.

When either of the two first compounds just described is dissolved in a large bulk of hot water, and the solution allowed to cool, solid white flakes are obtained containing more C and H, and less I, than the original substance. By repeating this treatment several times successively, the same ultimate compound appears to be produced in each case, being apparently formed by the reactions—

The removal of the last traces of basic HI is very difficult; it may be accelerated by adding a few drops of sodium carbonate to the boiling solution and filtering hot from the small amount of precipitated base; the product is apt, however, to be more strongly yellow coloured when obtained in this way than when got by treatment with water alone.

Specimen A. Got from compound C₆₈H₈₂I₂N₄O₁₀·4HI by water and a little sodium carbonate:—

0·366 grm. gave 0·672 CO₂ and 0·177 H₂O.

0·406 grm. gave 0·227 AgI.

Specimen B. From same compound by water alone:—

0·369 grm. gave 0·674 CO₂ and 0·174 H₂O.

0·4555 grm. gave 0·2675 AgI.

Specimen C. From compound C₆₈H₈₆I₂N₄O₁₂·4HI by water alone:—

0·4265 grm. gave 0·762 CO₂ and 0·220 H₂O.

0·3845 grm. gave 0·2275 AgI.

N ₄	56	4.70
O ₁₅	240	20.13

C₆₈H₈₀N₄O₁₀+O₅ 1192 100.00

From these numbers it appears that the free base, like bromo- and chloro-tetra-codeia, rapidly absorbs oxygen from the air.

Probably there exists a compound intermediate between the hydriodate just described and the original body—

thus one batch of flakes got by two treatments with water of this original substance gave the following numbers after drying at 100°:—

0.3225 grm. gave 0.556 CO₂ and 0.153 H₂O.

0.3205 grm. gave 0.212 AgI.

Another specimen obtained similarly—

0.4175 grm. gave 0.269 AgI.

	Calculated.	Found.
C ₆₈	816	47.02
H ₈₅	85	5.27

N ₄	56	3.20
O ₁₀	160	9.13

C₆₈H₈₁N₄O_{10.4}III 1752 100.00

It is not impossible that this substance is not a definite compound, but only a mixture; nevertheless, a free base of this composition and its hydriodate have been obtained by the action of sodium carbonate on the compound

from whence it appears probable that the body analysed is really a definite compound, formed by the reaction.

Both the final and intermediate products have a very curious structure under the microscope; although they stimulate in a high degree the appearance of crystals as they separate from a hot aqueous solution, yet on microscopic examination they are found to consist of strings of coalesced globules not unlike the yeast-plant. In qualitative reactions all the bodies hitherto described are very similar: ferric chloride gives no colouration to the aqueous solution of the hydriodate; silver nitrate is reduced on standing, producing a yellow tint; nitric acid gives an intense yellow; sulphuric acid and potassium dichromate only separate iodine; sodium carbonate throws down a white precipitate scarcely soluble in excess, and soon becoming yellow, salmon-colour, and finally dark brown; ammonia gives a similar precipitate somewhat more soluble in excess, while caustic potash readily dissolves the white precipitate first formed. In many of these reactions this group of codeia derivatives utterly differs from the bodies got by the action of HCl or HBr; most of these latter derivatives give colours with ferric chloride and sulphuric acid and dichromate; all give a blood-red with nitric acid, while the free bases turn more or less green by exposure to air.

On similarly treating with boiling water the compound C₆₈H₈₂I₂N₄O_{6.4}HI, formed by the action of hydriodic acid on codeia at about 130°, a substance similar in characters to that got from the other two compounds is produced; the final product, however, differs somewhat in its physical characters from those just mentioned; instead of coming out from the hot aqueous solution in solid flakes, it

appears in very minute solid oil globules which do not readily subside, and give to the liquid a great resemblance to fresh milk; sometimes the globules do not subside for many days.

Dried at 100° these globules give numbers indicating a compound analogous to that of the non-iodised base just described; it is, however, much more difficult in this instance to remove the last portions of basic HI; moreover, 4 molecules of water appear to be taken up, probably in lieu of the oxygen lost.

Specimen A. Original substance treated three times with large excess of water—

0.3315 grm. gave 0.589 CO₂ and 0.175 H₂O.

0.299 grm. gave 0.178 AgI.

Specimen B. Original with water four times—

0.321 grm. gave 0.585 CO₂ and 0.169 H₂O.

0.411 grm. gave 0.754 CO₂ and 0.218 H₂O.

0.2835 grm. gave 0.165 AgI.

Specimen C. Original with water five times—

0.4095 grm. gave 0.746 CO₂ and 0.219 H₂O.

0.3995 grm. gave 0.237 AgI.

C₆₈H₈₈N₄O_{10.4}HI.

Hence this compound is formed by the reaction

Carbonate of soda threw down from Specimen C. a white precipitate, becoming yellow on standing: this precipitate contained a small amount of iodine, showing (as the above numbers indicate) that the transformation of the original substance was not absolutely complete.

The qualitative reactions of this substance are the same as those of the bodies previously described.

(To be continued).

ON THE ESTIMATION OF NITROUS ACID IN NITRO-SULPHURIC ACID.

By GEORGE E. DAVIS.

On page 237 of this journal, Mr. W. Crowder gives a most important and interesting paper upon a subject which must be of great interest to all those interested in technical chemistry. I allude to the paper "On the Estimation of Nitrous Acid in the Commercial Gay-Lussac Acid."

In the month of May last it was part of my work to estimate the amount of nitro-compounds in our acid from the absorbing column daily. A method was put into my hands (which was imported from the Tyne) which was as follows:—

There was a graduated tube or pouret, divided into 100 parts, and etched on the side was 363 grs. 20 grs. of a 35 per cent bleaching-powder was now ground up and mixed with about a pint of water in a large flask; the pouret was filled up to O with the nitrous vitriol and gradually added with constant agitation until a few drops of indigo sulphate produced a permanent blue colouration.

This is the process as I received it, but I found that it was very inconvenient to have to keep and to weigh off every time 20 grs. of the bleaching-powder, so I set to

work and prepared a solution of which 10 c.c. contained exactly 7 grs. of chlorine. On the day upon which I seriously thought of preparing a large quantity of standard solution I met with a sample of bleaching liquor which contained exactly 7 per cent of chlorine; I took of this 10,000 grs. and diluted it to a litre, and prepared a Winchester quart of the solution. The process then became exceedingly rapid, as it was not protracted by the process of weighing, and an estimation occupied about three minutes.

If the number of measures used varied from 60 to 70 the acid was considered very good. In the few spare moments I then possessed my thoughts were, "What do those numbers mean?" but my time being so fully occupied the matter received no attention until the first week in June, when I began to investigate the subject, as I was struck with the similarity of the numbers obtained when the same samples were operated upon, as specimens I give from my note-book.—

	Sample α.	Sample β.	Sample γ.
1st trial	97	74	103
2nd "	97	76	101
3rd "	99	76	102
4th "	98	78	102

Now, the process I have always used for the estimation of nitrous acid (N_2O_3) has been the permanganate process (see Fresenius's "Quantitative Analysis," 1870, p. 166), so I thought I would try this latter process and see if the numbers obtained corresponded at all with the chloride of lime figures. They did not closely correspond, and from pressure of other business I was forced to give the subject up for awhile. I had spoken to several chemists on the subject, and they all agreed with me that the permanganate process seemed the most reliable.

In pursuing the investigation in August, I first thought it necessary to determine whether the nitro-compounds were wholly in the form of nitrogen-trioxide, although my reading, and the assertions of other chemists, assured me that that point had been already determined. Having assured myself that the nitrogen-trioxide alone was present, I commenced to use my decinormal solution of potassium permanganate, but owing to the organic matter which colours the brown vitriol, the end of the reaction is not very definite, the pink colour always going after standing for a few minutes; but if the colour lasts for two minutes I think it may be taken that all the nitrous acid is oxidised.

For one week in August I put down the number of c.c. used to 10 c.c. of the nitrous vitriol, by the side of the number of divisions of vitriol used from the pouret by the chloride of lime method. They were as follows:—

Chloride of lime method.	Permanganate $\frac{\text{N}}{10}$ No. of c.c. used.
78	64
71	76
87	59
99	52
89	68
86	61

When these numbers come to be considered it will be seen that there are irregularities which I have found it difficult to explain; for instance, 78 measures contained the nitrous acid which the 20 grs. of bleaching-powder would oxidise, and also the 64 c.c. of the $\frac{\text{N}}{10}$ permanganate, whilst in another case that quantity of nitrous acid was contained in 89 divisions of the pouret and required 65 divisions or c.c. of permanganate to oxidise it.

Now, the organic matter which colours the brown oil of vitriol of commerce is partly destroyed by the acid of high density; in fact, the partial destruction forming the colour, and this is readily acted upon by the permanganate; not but what all brown vitriol contains organic matter,

but some samples may contain a great deal more than others. Then, again, some vitriols may contain more arsenious compounds than others; but of course these would be equally acted upon by permanganate or chlorine.

Then there is another source of error in the permanganate process. It has been shown that a large excess of sulphuric acid interferes with the determination of iron by its use, and it might be supposed that a large quantity of acid would be injurious in this case; the dilution of the nitrous acid also affects the results.

I use the permanganate process thus:—

Take 10 c.c. of the nitrous vitriol and put it into a litre of water in a large flask and agitate it gently so that any nitrous acid which may be given off is again dissolved. This is again, I think, a source of error, for the nitrous acid is in contact with oxygen in the presence of water, and a slight oxidation might take place. When the solution has been prepared, the decinormal solution of permanganate is added until the solution is not decolourised after standing two minutes. This precaution was not taken in the experiments just cited, for the addition of permanganate was stopped directly immediate decolouration ceased, as I was afraid that the permanganate would be consumed by the organic matter.

Each c.c. of permanganate made by dissolving 3.162 grms. in the litre = 0.0019 grm. of nitrous acid (N_2O_3), the reaction which takes place being—

By following the above instructions results may be obtained which nearly coincide with the chloride of lime method. To return to this latter method. The reaction which takes place between chlorine and nitrous acid may be taken to be $\text{N}_2\text{O}_3 + \text{Cl}_2 + 3\text{H}_2\text{O} = 2\text{HNO}_3 + 4\text{HCl}$. 142 grs. of chlorine oxidising 76 grs. of nitrous acid into nitric acid.

By the equation—

$$\frac{7 \times 76}{142} = 3.74$$

we have the quantity of nitrous acid corresponding to the 20 grains of the 35 per cent bleaching-powder, or the 7 grs. of chlorine.

But the pouret contains 363 grs. of water; therefore to get the real weight we must, of course, take into consideration the specific gravity of the vitriol. Now, in the test experiments, with every precaution taken to ensure accuracy, the following results were obtained, the permanganate being added until the pink colour remained after standing two minutes:—

Chloride of lime method.	C.c. of permanganate used to 10 c.c. of nitrous vitriol.
85	60
85	60
87	57
85	58
86	55
Average, 85.6	58

Now, taking the numbers and expressing the results on the volume, which is the method used I believe in many manufactories, as it dispenses with weighing, we have 3.74 grains of nitrous acid in 85.6 measures of the vitriol, each measure corresponding to 3.63 grs. of water.

The following equation will then give us the percentage of nitrous acid if we leave the specific gravity of the solution out of the question:—

$$\frac{3.74 \times 100}{3.63 \times 85.6} = 1.203.$$

Turning now to the average of the permanganate numbers, let us see how it agrees with the chloride of lime average:—

$$\begin{aligned} \text{Each c.c. used} &= 0.0019 \text{ grm. of } \text{N}_2\text{O}_3; \\ 0.0019 \times 58 \times 10 &= 1.102 \text{ per cent } \text{N}_2\text{O}_3, \end{aligned}$$

and the specific gravity being 1.74 the true percentage on the weight is—

Chloride of lime process, 0.75 } of N_2O_3 .
Permanganate process, 0.63 }

Although I have said before that the organic matter of the vitriol might be acted upon by the permanganate more readily than the chlorine, yet, in this case, the permanganate gives lower results than the chloride of lime process, and that has led me to suppose that, on adding the nitrous vitriol in small quantity to the large quantity of water (containing, of course, dissolved oxygen), that oxidation takes place to a considerable extent. There is no gas left in the atmosphere of the flask after slight agitation, as with my experiments iodide of potassium and starch paper was not coloured in the slightest degree.

The five trials may then be tabulated thus:—

Chloride of lime, divisions of pourer.	Permanganate c.c.	Volumetric percentage by chloride process.	Volumetric percentage by permanganate.
85	60	1.212	1.140
85	60	1.212	1.140
87	57	1.184	1.083
85	58	1.212	1.102
86	55	1.198	1.045

It will thus be seen that the numbers and necessarily the percentage obtained by the chloride of lime process are very regular; but that method, even in my opinion, is very faulty, for directly the nitrous vitriol is poured into the chloride of lime, although it be greatly diluted, there is a large disengagement of chlorine, which of course is lost. I do not mean to say that such a large quantity is really lost, but that chlorine is escaping is soon rendered evident to the nasal organs, and even a small escape must affect the results.

In using the chloride of lime process it might be supposed that the standard solution of chloride of lime is quickly decomposed; this is not, however, the case if the solution is not directly exposed to the light and kept in a well-stoppered bottle. The first Winchester quart I prepared contained 7 grains of chlorine in 10 c.c.; after one month it was still 7 grs., and after two months, when the bottle was nearly empty, 10 c.c. contained 6.89 grs.

The sources of error in the permanganate process could, I believe, be reduced to a minimum if the nitrous vitriol was added to the permanganate solution. I have these experiments going on now, and I hope soon to lay the results before your readers.

Laboratory, R. Bealey and Co.,
Radcliffe, Manchester.

NOTES OF

DEMONSTRATIONS ON PHYSIOLOGICAL CHEMISTRY AT ST. GEORGE'S HOSPITAL.

By S. W. MOORE.

V.

FATS are compound ethers of the triatomic alcohol glycerine—

Bases combine with the fatty acids contained in fats and oils, setting free glycerine and forming soap. Steam forced into fats at high pressure decomposes them, forming glycerine and fatty acids; the former being soluble in water is readily separated.

The rancidity of fats is due to an albuminous ferment setting free certain fatty acids present only in small proportions, such as butyric acid; this rancidity may be removed by washing with water, as the acids producing it are all soluble in that fluid.

Some oils absorb O and form varnishes; this property is called drying: cod-liver oil is the only animal oil acting thus. Oils, and, in fact, most fluids insoluble in water,

form when dropped on that liquid figures called by Tomlinson (and described by him fully in his "Cyclopædia of Arts") cohesion figures; each distinct oil has a separate cohesion form, and by a practised eye an admixture of inferior oil may readily be seen when this experiment is performed; the vessel of water should be 6 inches in diameter and a small-bore pipette used to drop the oil from.

The proximate constituents of fats are olein, stearin, palmitin, and margarin. Olein is the fluid portion of oils, and does not solidify at 0° C. Stearin ($\text{C}_{57}\text{H}_{110}\text{O}_6$), a solid fat contained in mutton suet, soluble in boiling alcohol; separates on cooling. Palmitin ($\text{C}_{51}\text{H}_{98}\text{O}_8$) is another solid fat contained in bees'-wax, and is obtained by crystallisation from an ethereal solution. Margarip, according to Heintz, is a compound of palmitic and stearic acids.

Natural Animal Fats and Oils.

Sperm oil and whale oil are unimportant.

Cod-liver oil has an importance due to its ready assimilation by the emaciated system of the phthisical patient. This property is due most probably to the bile contained in the oil. It consists chiefly of olein, some acetin, phosphorised fat, I, and Br; the two latter elements may be detected by saponification with KHO, evaporation, incineration, dissolving the ash in water, and testing with suitable reagents. H_2SO_4 acts on the bile resins, giving a crimson colour to the oil.

Butter consists of olein and palmitin, with butyrin, caproin, and caprylin; or, saponification the corresponding acids are set free, known by their characteristic pungent odour.

Lard contains mostly olein. Suet contains stearin.

Spermaceti, a solid crystalline fat obtained from the sperm whale, does not yield glycerine when saponified, but ethal ($\text{C}_{16}\text{H}_{34}\text{O}$).

Bees'-wax consists of cerolein, soluble in cold alcohol, and to which the tenacity and odour of wax is due; cerotic acid, soluble in hot alcohol; and myricin, insoluble in alcohol. This latter is a mixture of a complex nature; the colour of wax is due to this.

Cholesterin ($\text{C}_{26}\text{H}_{44}\text{O}_2$). This fat does not saponify; it is contained in bile, the liver, brain, and gall-stones; it crystallises from a solution in alcohol in rhombic plates.

The melting-point of a fat may be ascertained by introducing a capillary tube charged with the fat under consideration into melting paraffin in which a thermometer is placed; as soon as the fat in the tube melts, observe the temperature denoted by the thermometer, and the result is obtained. To charge a capillary tube with fat, melt the material and plunge in the end of the tube; when the melting fat is drawn up remove it, and as soon as it is cold the determinations may be made.

Fatty matters are soluble in ether and benzol.

ON THE

METHOD OF ASSAYING SILVER ADOPTED IN THE

ASSAY OFFICES OF H.M. INDIAN MINTS.*

By H. E. BUSTEED, M.D.,

H.M. Madras Army, Officiating Assay Master, Calcutta Mint.

(Concluded from p. 246).

WITH regard to the weight of the small portion taken to represent the mass, the system prevails in the Indian mints of taking samples for assay by granulating a small portion of the contents of each melting-pot; when the metal is in a thorough state of fusion and has just been well stirred, a small ladleful of the molten metal is quickly poured from a tolerable height into a vessel of water, and the granules so formed received on a strainer, lifted out

* From the Journal of the Asiatic Society of Bengal.

and perfectly dried.* The weight of this specimen representing each pot was at first fixed at 24 grs., technically called the "assay pound;" this in the case of pure silver yielded 31.87 grs. of chloride of silver, while the same quantity of Indian standard silver (which is $\frac{1}{11}$ ths silver plus $\frac{1}{11}$ th copper = 916.66 in 1000) yielded one-twelfth less, or 29.21 grs.; on the weight of chloride being ascertained in each case a table which was calculated and prepared for the purpose was referred to and the equivalent fineness assigned to the $\frac{1}{4}$ dwt., plus the odd grs., when any. But when it became desirable to prepare for the decimal form of notation, a number more convenient than 31.87 was looked for to represent purity or 1000, and 25 was fixed on as a desirable starting-point, particularly as the quantity of pure silver yielding that amount of chloride, viz., 18.825 grs., was quite large enough to represent each pot.†

The weight, therefore, of the "assay pound" in use at present is 18.825 grs. This produces (with chlorine) in the case of pure silver 25 grs. of chloride of silver.‡

But to obviate the necessity of constant reference to a calculated table to find the equivalent in pure silver of the amount of chloride of silver found in each case, it was ingeniously arranged to stamp each of the assay weights not with its actual weight, but with the figures representing the proportion per mille of pure metal which such a weight of chloride so found corresponds to; thus, supposing a melting of five-franc pieces was being assayed, and the chloride resulting from the assay pound operated on, weighed 22.5 grs. (showing the actual pure contents in the sample to be 16.94 grs.), instead of referring to a table to see the equivalent per mille-age of pure silver, that weight which is actually 22.5 grs. has 900 marked on it, and the assayer simply reads the touch from it.

Accordingly the assay weights are as follows:—

Actual weight in Grs.	Figures marked on the weights.
25.000	1000.00
22.910	(Std.) 916.66
22.500	900.00
20.000	800.00
17.500	700.00
15.000	600.00
12.500	500.00
10.000	400.00
7.500	300.00
5.000	200.00
2.500	100.00
1.250	50.00
1.000	40.00
0.750	30.00
0.500	20.00
0.250	10.00
0.125	5.00
0.100	4.00
0.075	3.00
0.050	2.00
0.025	1.00

Assay lb., weight = 18.825 grs.

* The introduction into the Calcutta Mint of this system of taking molasses is, I find, attributable to Dr. Boycott, late Assay Master, and to Dr. Sherketon, who, by a number of interesting experiments, satisfied themselves that samples so taken represent the mass of mixed metal to be valued much more fairly than samples of the same mass cut or gouged from it after it has been poured and allowed to cool in the ingot moulds where a partial separation of the copper from the silver seems to take place; the result being, according to the above experiments, that in the case of ingots cast in upright moulds, all the outside is much below the average fineness of the mass on assay, and the centre much above it. This refers to alloys of silver and copper mixed in or about the proportion of "standard." According to Monsieur Levot, however, it would appear that when an alloy of silver and copper in which the proportion of the latter is very high (viz., over 28 per cent) has been melted, poured, and allowed to cool, an opposite result to the above is found, viz., the outside of the ingots is above the average fineness. An assay therefrom from a granulated sample must give a much nearer approximation to truth than one from a cut sample.

† The average weight of the contents of each melting-pot is 12,500 tolas, or about 390 pounds Troy, so that the specimen taken to represent this is but about the 119,000th part; each sample is assayed in duplicate.

‡ The basis for these numbers was founded on the proportion in which, according to Turner, silver combines with chlorine, viz., 100 parts with 32.80.

The assays for the valuation of merchants' bullion are reported to the $\frac{1}{1000}$ th part, i.e., the value of our smallest weight, and as the distance from zero to the point (shown by a scale and indicator) at which the balance "breaks" with this weight in either pan is sub-divided into five, the decimals over or under one-thousandth can be read off.

Accordingly assays are reported to the mint office (as a matter of interior economy, for facilitating the alligation arrangements) to 0.4 and 0.6 (e.g. "997.4": "900.6"), and the assays of the standard meltings and of the local pyx coins are reported to 0.2. Thus, reports are made with confidence by this process to a little over 1 gr. (1.152) in the troy pound.

Though the whole process can be carried through to completion in the case of a small number of assays within twenty-four hours, still in the ordinary heavy current work of the office, assays are not completed till the third day. Thus, the samples are tendered suppose on Monday; they are "weighed in," dissolved, and precipitated on that day; on the next they are washed and syphoned twice; and on Wednesday they are "potted," dried, and reported. The certificates of value (payable on demand at the Government Bank) are examined and signed by the assay master on the following morning and handed to the merchant or his agent. In like manner samples tendered on Tuesday are, under ordinary circumstances, weighed and reported by the assay master on Thursday, and so the work goes on steadily, under a systematised routine, where each hour has its assigned duty.*

An ordinary day-work consists of eighty assays,† estimating imported bullion to the value of four lacs of rupees, and standard meltings and coins to the value of five lacs. But on emergencies, in time of heavy pressure, by working extra hours, as many as 164 assays have been daily conducted, estimating bullion to the value of eight lacs of rupees, and standard coins and meltings to the value of fourteen lacs.

Such is an outline of the method of assay worked on a large scale; of course successful results from it cannot be expected unless each step in the manipulation be conducted with great care and accuracy, and only then after much practice and experience.

The natives of this country possess great aptitude in acquiring the skill and confident lightness of touch so essential for delicate manipulation; this, added to their characteristic patience, makes them admirable subordinates in an assay laboratory, under judicious supervision; moreover, their labour is cheap; so that, on the whole, the process seems to be especially suitable for an Indian mint.

When bar silver is imported from the Continent, the assays of it, made here, almost invariably correspond most closely with those previously made of it in Paris by the volumetric method. But were further proof needed of the practical accuracy of our system, it is to be found in the very close proximity to the legal standard, at which the large Indian coinage has been maintained for many years, as annually reported by the assayers to the Royal Mint of Great Britain, who test the fineness of the Indian pyx coins by the French humid process.

* When holidays or Sundays intervene, the current work is so arranged that the chlorides are not allowed to remain an undue time exposed in the bottles, more especially after the second syphoning, when a minimum of acid is present; under such circumstances, the chlorides are found to lose somewhat in weight, becoming finely divided, easily broken, and showing a tendency to adhere to the cups; similar results from allowing the chlorides to remain in the bottles with insufficiency of acid have been found to follow even when the bottles have been the whole time secluded from light. Syphoning too low must also, for similar reasons, be guarded against.

† Exclusive of any gold assays which may be going on.

* The Calcutta Assay Office has been been fortunate in the possession of its Foreman, Mr. Frewin, who, for over 30 years has been actively engaged in assay operations. He was head assistant in the office under Mr. Dodd when the latter was investigating the adaptation of this system, and no doubt Mr. Frewin's intelligence and dexterity contributed to its successful introduction and subsequent working; he has trained numerous subordinates to the laboratory work who have turned out expert manipulators.

Without this method (improved and made more perfect, as it has been, in the hands of successive assay officers), it would, to my mind, have been very difficult for the assay establishments of the Indian mints to have dealt with, in the same time and with the same accuracy, the immense importation of silver to India during the last fifteen years. In the single year 1865-66, there was poured into the Indian mints, and manufactured into coin, silver alone reaching in value to the prodigious amount of over fourteen millions sterling.

The system which enabled the assay officers to value such a rapid and heavy influx with accuracy, and with satisfaction to the importer on the one hand and to the mint (the buyer) on the other, and to faithfully maintain the immense resulting coinage close to legal standard, has been put to a severe test. If success be the criterion of merit, the 20 years' large experience of this method gained in the Indian mints goes, I think, to show that it is worthy of a yet wider field of utility.

Appendix.

(1.) The bottles used in this process are of thin (but strong) white glass and contain about 12 fluid ozs.; about six inches in height and $2\frac{1}{2}$ inches in diameter at the bottom, which should present a perfectly even, level floor; they are without any (abrupt) shoulder, but become gradually pyramidal from about half way up to the neck; this shape favours the easy dropping out of the chloride. The neck is about one inch in length, polished on its inner surface; the stoppers are of ground glass, polished, with globular heads, and are made to fit with the utmost accuracy and smoothness. The bottles and stoppers are numbered, to correspond with the number on the muster board and also on the cups.

(2.) The "cups" are Wedgwood crucibles, smooth and thin, about $1\frac{1}{2}$ inches in height, $1\frac{1}{2}$ inches in diameter above, and a little less than 1 inch in outside diameter at the bottom. The floor should be perfectly level, and neither it nor the sides should present any roughness likely to retain the chloride. The cups are all numbered.

(3.) The porcelain saucers are shallow, $\frac{3}{4}$ of an inch in depth; the upper diameter is about 4 inches, the lower $2\frac{1}{2}$ inches.

(4.) The turn-table is a circular board of about 3 feet in diameter, fenced by a brass railing (or by a simple ledge); its centre is occupied by a raised platform about 2 feet in diameter, between which and the rail the bottles (26 on each) stand, the round outer edge of the platform having semi-lunar niches cut in it, into which the bottles fit; opposite to each niche on the platform is a little concavity in which the stoppers rest when not in the bottles. Each turn-table is made to revolve on its centre in either direction, and is raised about 6 inches above the long general table on which all are supported; close to each a funnel is fitted into the lower (supporting) table for conducting away the fluid syphoned from each set of bottles.

(5.) The trough is a basin of cast-iron (painted); it may be oblong or round, raised to about the height of 3 feet from the ground; when round and large enough for twenty bottles, space and distilled water may be economised by having a platform insulated in the centre. This is convenient for resting the bottles on after the chlorides have been got out. A trough of this kind may be about $2\frac{1}{2}$ feet in diameter, having a space 7 inches broad and 4 deep all round between the circumference of the basin itself and the outer edge of the island platform. Into this space is poured distilled water to the depth of 3 inches. From the rim of the trough hang as many brass supports as there are bottles to be inverted; these are two circular clasps connected at the back to a bar common to both; one, the larger, is $1\frac{1}{2}$ inches above the smaller and lower one, which is under water; they are open in front (or towards the centre of the basin) to about $\frac{3}{4}$ of an inch in width. The openings of both are in the same line, owing

to the lower (smaller) segment being projected towards the centre by an abrupt curve in the connecting bar, by which they hang from the brim. This arrangement receives and fixes the inverted bottles in the required position. The distilled water is removed from the trough by the withdrawal of a plug. These troughs are sometimes made to revolve on the centre.

(6.) The drop bottle used for washing down the glass rod when breaking up the chlorides, and for sprinkling the surface of the cups, in small sized, round, so as to be easily grasped; it holds about 6 ozs. The stopper is hollow, with two small tubes leading from its head, one opposite to the other. Glass is so liable to break or chip that a hollow silver stopper is now generally substituted.

(7.) The steam-bath is simply a square vessel made of sheet copper, between 3 and 4 inches deep, the top or upper plate of which has a number of circular openings about two-thirds of the diameter of a Wedgwood crucible. There is also a steam escape pipe leading from the centre below to about a foot in height. They are of various sizes to contain from 10 to 150 pots: they are raised or moved by two lateral handles.

(8.) Hot air plate of thin sheet iron bored with holes for the reception of the crucibles, raised by iron feet about $1\frac{1}{2}$ inches above the furnace plate. It is furnished with a square tin cover which fits over it. This is provided with lateral apertures for the escape of heated air, and with a tube from its roof for the reception of a thermometer.

The drying furnace on which the above rest is surmounted by a hood, the door of which (glazed) slides up and down by weights and pulleys; the plate is heated by means of gas jets; it has a good draught to carry off the nitrous fumes, as on it the musters are dissolved in the first instance on a sand bath.

(9.) The forceps for removing the cake of chloride from each cup to the skiff of the balance should not be too sharp in its grasp; it is much improved by having the blades tipped for about an inch from the points with platinum about $\frac{1}{2}$ inch in width.

(10.) It is a convenience to have the assay weights arranged in a set of ivory compartments in the weight box; on the floor of each compartment are engraved the figures corresponding to those engraved on the weight which occupies it; by this means the assayer has merely to glance at his weight box to see what weights are in the pan of the balance, and to read off the "touch" when each chloride is counterpoised.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

November 16th, 1871.

Mr. RILEY, whose remarks were not fully reported in our notice of the proceedings of the Chemical Society last week, has forwarded the following statement for publication:—

Mr. Riley was sorry he only heard the latter part of the paper just read, and said that the mechanical treatment of iron should be considered quite as much as the chemical composition of the iron. Thus iron that was quite brittle, such as puddler's old rables, when piled, heated, and rolled two or three times, became fibrous to a certain extent, and much improved in quality. The best fibrous wrought-iron, after being melted, became very red-short.

Much misconception existed as to the injurious action of the so-called impurities in iron.

He found that excellent tool steel that worked well under the hammer and stood the severest tests (burning off

the skin of cast-steel wheels) contained an amount of silicon that would be very prejudicial in white cast-iron, and make it difficult to puddle.

In reply to Dr. Odling's queries as to sulphur and phosphorus, he considered sulphur mostly injurious, although it made No. 1 pig stronger (the most highly graphitic iron) by reducing it to Nos. 3 or 4, less graphitic pig, which was a stronger iron.

No one would, however, think of using sulphur, as the highly graphitic iron being the most difficult and expensive to produce, there was always sufficient of a lower quality (white or mottled) to mix with No. 1 pig so as to reduce it to Nos. 3 or 4.

He considered that in pig-iron, a certain amount of phosphorus was advantageous, as without it the iron, when puddled, worked red-short; thus the best Swedish pig made a red-short iron, and its quality would be improved by mixing a lower quality containing phosphorus with it, such as Cleveland or Derbyshire pig.

Low Moor and Bowling pig contains uniformly about 0.64 per cent of phosphorus, the amount being the same generally when the best clay iron-stones are used in South Wales either with hot or cold blast; there was no doubt that such pig made the best wrought-iron, and commanded a higher price than Swedish charcoal pig.

Phosphorus in steel is certainly injurious, and anything much over 0.10 per cent he considered very detrimental. The sample referred to contained 2.07 per cent of silicon.

In puddling iron he considered it was essential to have some silicon in the pig; good white forge pig usually contains from $\frac{1}{4}$ to 1 per cent, whereas inferior white pig frequently contains only 2-roths to 3-roths per cent.

Tungsten is being used by Mr. Mushet in his so-called "special" steel; it contains more than 10 per cent, and is an excellent steel for certain kinds of cutting tools; it requires no hardening.

CORRESPONDENCE.

HEAT AND ELECTRICITY.

To the Editor of the Chemical News.

SIR,—It is doubtless true that the heating power of a current is proportional to the square of its strength; but, unless I misunderstand Mr. Highton, he did not measure the strengths of the currents employed to heat his wires at all. He measured the currents given by the cells acting against the small resistance of his tangent galvanometer, but surely he does not suppose that the ratio between the currents will remain the same when the resistance of the circuit is altered by introducing a thin wire. That it should do so it would be necessary that the electro-motive forces of the cells should be alike. A single Grove cell will give the same deflection of a tangent galvanometer needle as ten or fifty similar cells, but the heating power will be very different.

Let Mr. Highton repeat his experiments introducing the galvanometer into the same circuit with the red-hot wire; he will then, I think, get a result more in accordance with the rule.—I am, &c.,

W. J. WILSON.

Birkbeck Institution, Nov. 27, 1871.

DUMAS'S VAPOUR DENSITY DETERMINATIONS.

To the Editor of the Chemical News.

SIR,—I shall be glad if you will grant me a little space in your journal to notice two errors with reference to Dumas's "Vapour Density Determinations," to be found in most of the text-books which treat of the subject, which I mentioned in the *Journal of the Chemical Society* last year, but to which Dr. W. M. Watts has again called attention in your issue of November 10th.

The first error alluded to is that no directions are given to observe the atmospheric temperature and pressure at the second weighing. This error has, no doubt, crept in and remained unnoticed owing to the fact that, as a rule, the height of the barometer and the temperature of the balance room would not vary perceptibly in the short time required for a determination, and that they would therefore be practically the same at both weighings.

Dumas's bulbs displace 10 to 20 c.c. of air, which weigh under ordinary circumstances 12 to 24 milligrammes (not by any means an *extremely small* quantity), but this quantity may be disregarded except in extreme cases, seeing that a variation of 5° C. in the temperature or 12 m.m. in the pressure will only affect the apparent weight of the bulb to the extent of 0.2 to 0.4 milligrammes. If, however, it is necessary to make allowance for variation of temperature or pressure the following correction must be applied to the formula:—

Let P = apparent weight of globe at t° C. and H m.m.
 P' = apparent weight of globe and vapour at t'° and H' .
 D = density of material of which the globe is composed (water = 1).
 (αH) = weight of c.c. of air at t° and H .
 $(\alpha' H')$ = weight of c.c. of air at t'° and H' .
 V = capacity of globe in c.c.
 v = volume of residual air.

Then the absolute weight of globe = $P + \frac{P}{D}(\alpha H)$.

And the absolute weight of globe and vapour =

$$P' + (V - v)(\alpha' H') + \frac{P}{D}(\alpha' H').$$

And the absolute weight of vapour =

$$(P' - P) + (V - v)(\alpha' H') + \frac{P}{D}((\alpha' H') - (\alpha H)).$$

Which only differs from the numerator of the Dumas formula by the quantity $\frac{P}{D}((\alpha' H') - (\alpha H))$.

The second error alluded to is that an incorrect expression is given for the actual weight of the bulb. This error is liable to mislead the student, although it will not affect the result, as it does not occur in the formula for the density but only in the verbose explanations. Those, therefore, who use the formula without troubling themselves about its construction will not introduce the error into their work.

If absolute accuracy were required in weighing, and if the balances generally used would weigh to 0.005 milligramme, it would, of course, be necessary to take into account the effect of the atmospheric variations on the apparent value of the weights themselves.—I am, &c.,

JAMES J. BROWN.

Sudbury, Harrow,
Nov. 21, 1871.

MISCELLANEOUS.

The Royal Society.—The annual meeting of the Fellows of this society was held yesterday at Burlington House, when Lieut.-General Sir Edward Sabine, R.A., K.C.B., resigned the high office of President, which he has so worthily filled since 1861, and the Astronomer Royal, who, by his untiring zeal and energy, has contributed largely to the advancement of science, was elected to fill the Presidential Chair. The Copley Medal was awarded to Dr. Julius Robert Mayer, and the two Royal Medals were presented to Drs. Stenhouse and Busk. The following gentlemen were appointed officers and council for the ensuing year:—*President*—George Biddell Airy, M.A., D.C.L., LL.D., Astronomer Royal. *Treasurer*—William Spottiswoode, M.A. *Secretaries*—William Sharpey, M.D., LL.D.; Professor George Gabriel Stokes, M.A., D.C.L.,

LL.D. *Foreign Secretary*—Professor William Hallowes Miller, M.A., LL.D. *Other Members of the Council*—George James Allman, M.D.; John Ball, M.A.; George Burrows, M.D.; Mr. George Busk, P.R.C.S.; Professor Robert Bellamy Clifton, M.A.; Heinrich Debus, Ph.D.; Professor Peter Martin Duncan, M.B.; Professor George Carey Foster, B.A.; Mr. Francis Galton; Thomas Archer Hirst, Ph.D.; Sir John Lubbock, Bart; Sir James Paget, Bart., D.C.L.; The Earl of Rosse, D.C.L.; General Sir E. Sabine, R.A., K.C.B.; Isaac Todhunter, M.A.; Sir Charles Wheatstone, D.C.L.

Royal Institution of Great Britain.—The following are the Lecture arrangements for 1871-72:—The Christmas Lectures, adapted to a juvenile auditory, will be delivered by Prof. Tyndall, LL.D., F.R.S., "On Ice, Water, Vapour, and Air," on December 28, 30, 1871; January 2, 4, 6, 9, 1872, at three o'clock. The other lectures before Easter, 1872, are:—Ten lectures "On the Nervous and Circulatory Systems," by Dr. W. Rutherford, F.R.S.E., on Tuesdays, January 16 to March 19. Ten lectures "On the Chemistry of Alkalies and Alkali Manufacture," by Professor Odling, F.R.S., on Thursdays, January 18 to March 21. Six lectures "On Literature," by W. G. Donne, Esq., on Saturdays, January 20 to February 24. Four lectures "On Demonology," by Moncure D. Conway, Esq., on Saturdays, March 2 to 23. The Friday Evening Discourses before Easter will probably be given by Mr. W. R. Grove, Q.C., the Archbishop of Westminster, Professors Odling and Humphry, Dr. Gladstone, Messrs. C. W. Siemens, R. Liebreich, and John Evans, and Professor Tyndall; the first meeting will be on January 13, 1872. After Easter the lectures will comprise—Three lectures "On Statistics, Social Science, and Political Economy," by Dr. Wm. A. Guy, F.R.S., on Tuesdays, April 9, 16, and 23. Six lectures "On the Development of Belief and Custom amongst the Lower Races of Mankind," by Ed. B. Tylor, Esq., F.R.S., on Tuesdays, April 30 to June 4. Nine lectures, by Professor Tyndall, LL.D., F.R.S., on Thursdays, April 11 to June 6. Five lectures "On Star Depths," by R. A. Proctor, Esq., B.A., F.R.A.S., on Saturdays, April 13 to May 11. Four lectures "On the Chemical Action of Light," by Professor Roscoe, F.R.S., on Saturdays, May 18 to June 8.

The Royal Polytechnic.—On Monday evening last, Mr. T. W. Tobin, who was captain of Mr. Streeter's expedition to the diamond fields of South Africa, delivered an exhaustive lecture on this discovery. Mr. Tobin's practical knowledge of the subject, together with his series of original sketches and the specimens of diamonds, rubies, and garnets (which were magnified), made the lecture an instructive one, and from the applause which followed its delivery it was evident that the large audience was much interested. Professor Pepper presided, and during the lecture practically demonstrated that the diamond is identical in composition with ordinary charcoal. The lecture will, we believe, be repeated daily.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 15, 1871.

This number contains the following original papers and memoirs:—Contribution to our Knowledge of the Cinchona Barks.—O. Hesse.—In the introduction to this paper, the author calls attention to the fact that Gräbi's test for detecting the genuineness of cinchona

barks does not rigorously apply, inasmuch as with any bark which contains more or less of the cinchona alkaloids—even though such bark be not, in botanical and pharmacognostical sense, a cinchona bark—the reaction discovered by Gräbi is observed. The reaction alluded to is that when a piece of a cinchona bark, or one which contains cinchona alkaloids, is gently heated in a test-tube held in a horizontal position, so that it gives off tarry matter, that fluid is carmine-red coloured, a reaction which Batta states always takes place when cinchona alkaloids are heated along with pure cellulose. The greater portion of this paper is devoted to the description of the results of some experiments made with a new kind of cinchona bark, which has been named *China cuprea* on account of its fine red colour, bluish red in the state of powder. The ammoniacal solution of this bark has a purple-red colour; this solution tinges white filtering-paper rose-red. The tannic acid present in this bark appears to be different from that found in the genuine cinchona barks; the quantity of alkaloids found in this bark amounts to from 2.12 to 2.25 per cent, viz.:—Quinine (pure alkaloid), 1.26; conchinin, 0.46; cinchonin, 0.22; amorphous bases, 0.34; chiniidin and paricin are not as yet found in the *China cuprea*; the amorphous bases are present as such in this bark, and are not the result of decomposition of other alkaloids by the action of reagents.

New Base from Strychnine.—A. Strecker.—3 parts of finely pulverised strychnine and 1 part of monochloroacetic acid were first heated to 180° for a period of four to five hours. The cooled mass, having been dissolved in water, was saturated with ammonia, and the mixture filtered, the filtrate yielding, on evaporation, a crystalline mass, the new base, a body difficultly soluble in cold but more readily so in hot water, also in alcohol, but not at all in ether. On analysis, results were obtained leading to the formula $C_{22}H_{24}N_2O_4$, confirmed by the analysis of the platinum double salt of this substance, which yields with acids salts, some of which (the nitrate and oxalate) are very difficultly soluble in water. The formation of this base is illustrated by the following formula:—

This base is distinguished from brucine by 2H less, while the new base contains C_2H_5O , more, than strychnine. With bichromate of potassa and concentrated sulphuric acid, this new base yields the same reaction as strychnine. Taking the constitutional formula of strychnine as—

the constitutional formula of the new base is—

and the name of the new base is glycol-strychnine.

On Hexyl-Alcohol from Heracleum Oil.—A. Franchimont and Th. Zincke.—After first referring at some length to some former experiments on this subject, the authors describe a series of experiments made with Heracleum oil, from which they obtained by fractional distillation and treating with alcoholic potassa solution, a hexyl-alcohol, $C_6H_{13}O$, a liquid not miscible with water; sp. gr. = 0.819; boils at 156°6'; by oxidation, it yields an acid containing the same quantity of carbon. The hexyl-iodide, the acetate, and the capronate of this body have been prepared by the authors, and described. The iodide, $C_6H_{13}I$, is a colorless liquid, insoluble in water, but miscible with alcohol and ether; sp. gr. = 1.4175; boils at 179°5'. The acetate, $C_6H_{13}(C_2H_3O)$, is a very pleasant-smelling fluid; sp. gr. = 0.889; boils at 168°7'. The capronate, $C_6H_{13}(C_6H_{11}O)_2$, is a fluid oil almost devoid of smell; sp. gr. = 0.865; boils at 245°6'. From carefully-made comparative researches, the authors infer that the hexyl-alcohol alluded to is a hitherto unknown body.

Researches on the Invisible Photographic Image.—H. Vogel.—We regret that it is not possible to give an abstract of this excellent paper, owing to the fact that it would require the reproduction of a large number of formulae.

Decomposition of Nitric Acid by Heat.—L. Carius.—This lengthy and exhaustive essay, being illustrated by a woodcut and several tabulated forms exhibiting results of experiments, does not admit of any suitable abstraction, notwithstanding its intrinsic merits.

Some Nitrogenous Compounds of Milk-Sugar.—R. Sachsse.—After briefly referring to the experiments made by Dusart, Thenard, and Schützenberger, on the action of ammonia upon the carbohydrates, the author gives a preliminary account of some experiments made by him on the action of aniline upon carbohydrates, and, in the first place, upon milk-sugar: hereby are at least two different compounds formed; one of these was found, by elementary analysis, to give results leading to the formula $C_{30}H_{40}NO_{21}$, while the other's formula was ascertained to be $C_{30}H_{44}N_2O_{20}$. The formation of these bodies may be illustrated by the following formulae:—

Contribution to our Knowledge on the Benzoin Series.—Th. Zincke.—An exhaustive and very lengthy memoir on the constitutional formulae of this very extensive series. Notwithstanding the very great scientific value of this essay, its contents, elucidated by a large number of complex formulae, are not suited for abstraction.

Application of the Second Main Point of the Mechanical Theory of Heat to Chemical Phenomena.—A. Horstmann.

Acetnaphthalid and some of its Derivatives.—P. Rother.—Acetnaphthalid ($C_{10}H_7.NH.C_2H_3O$), obtained by heating for several consecutive days naphthylamine and glacial acetic acid, is a solid crystalline body, insoluble in cold, readily soluble in hot, water and alcohol; fuses at 159° ; treated with fuming nitric acid in the cold, it yields binitro-acetnaphthalid ($C_{10}H_5(NO_2)_2.NH.C_2H_3O$). This new compound is almost totally insoluble in water either cold or hot, soluble in alcohol, but insoluble in ether, benzol, chloroform, and glacial acetic acid. Acetnaphthalid combines with bromine, forming a monobromide ($C_{10}H_6Br.NH.C_2H_3O$), insoluble in water, but soluble in boiling alcohol; from the alcoholic solution this body crystallises readily. By the action of caustic potassa solution on this last compound, there is formed monobrom-naphthylamin ($C_{10}H_6Br.NH_2$), fusing at 94° , and combining with acids to form salts.

Preliminary Notice on the Reaction between Oxychloride of Phosphorus and Phosphoric Anhydride.—G. Gustavson.—When equivalent quantities of phosphoric anhydride and oxychloride of phosphorus are heated in a sealed tube at 200° for some thirty-six hours, there is formed a thickish transparent mass, probably the chloride of the metaphosphoric acid, formed according to the following formula:— $P_2O_5 + POCl_3 = 3PO_3Cl$. The author is still engaged in these experiments.

La Revue des Scientifique de la France et de l'Etranger,
November 11, 1871.

This number does not contain any original papers on chemistry, but we call attention to the following excellent memoirs:—

Freedom of Superior Instruction.—M. Lorain.—A well written and digested essay on the higher branches of education, and the duties of the state in respect thereof.

Poisoning with Carbonic Oxide Gas.—M. Gréhaut.—This memoir, illustrated by engravings, is an excellent specimen of experimental physiology, as taught by the author at the Practical Lectures of the Medical Faculty of Paris.

November 18, 1871.

In addition to an essay to be presently more fully alluded to, this number contains the following original papers which, although not strictly relating to chemistry, deserve attention:—

Middle Class Education in France.—M. Lorain.

The Regulators (Régulateurs) of Human Life in a Physiological Sense.—Dr. J. Moleschott.—This is the author's opening lecture of his course of physiology at the University of Turin; for clearness, distinctness, and eloquent mode of treating the subject (a general review of the principal functions of the human body), this lecture deserves the attention of all interested in this matter.

Excretion of Urea by the Kidneys.—Dr. Gréhaut.—A great portion of this lecture is devoted to anatomy and physiology, but, speaking of the quantitative estimation of urea, the author states that he has improved Millon's process for this purpose, the advantages of the author's mode of operating being that—(1). It is not necessary that the urea be pure; it may be even contaminated with albuminoid matters, salts, and fatty matters. (2). No weighing is required, since the gases (nitrogen and carbonic oxide) resulting from the decomposition of the urea are completely collected in graduated tubes. (3). The process is very correct, because the author's apparatus (unfortunately this cannot be well understood without reproduction of woodcuts) enables the operation to be performed in a vacuum, and even 1 centim. of urea may be successfully operated upon. This excellent and very complete paper also treats on the estimation and detection of urea in blood, while, moreover, an ingenious apparatus for accelerating evaporation of liquids at a high temperature is described and illustrated by an engraving.

November 25, 1871.

This number does not contain any original papers relating to chemistry, but we must not omit to quote the title of the following essay:—

Electric Properties of the Nerves and Muscles During the State of Embryonic Life and During the State of Putrefaction.—Dr. Valentin.—An experimental physiological essay.

Polytechnisches Journal von Dingler, second number for October, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied subjects:—

Studies on Blast-Furnaces and Pig-Iron Production.—C. Schinz.—Continuation of this exhaustive memoir. This portion consists of a series of tabulated forms exhibiting the results obtained by the actual working of blast-furnaces.

Volumetric Estimation of Iron and Ferrocyanogen.—H. Rheineck.—This paper treats on the quantitative estimation of iron and Berlin blue in liquids used in dye-works, but the contents are not suited for any useful abstraction.

Method for Testing Bleaching-Powder (Hypochlorite of Lime).—Dr. Graeger.—The author prepares a very dilute and strongly acidified solution of protosulphate of iron, which is exactly titrated with 1-20th solution of permanganate of potassa. Into this solution, kept in a bottle, the solution of bleaching powder is poured by the aid of a pipette, and, the bottle having been stoppered, the mixture is shaken up, and afterwards the undecomposed iron salt estimated by

the aid of permanganate; 100 c.c. of that solution correspond to 3.546 grms. chlorine and to 0.8 grm. oxygen. To 1 grm. of bleaching-powder, considered as containing 3.3546 grms. chlorine, is required 0.278 grm. sulphate of iron, but it is best to take 0.4 to 0.5 grms. of that salt. The ammonio-sulphate of iron cannot be used on account of the danger consequent upon the formation of chloride of nitrogen.

Extraction of Sugar from Molasses by the Aid of Baryta.—Dr. G. Lunge.—An excellent practical treatise on this subject. Saccharate of baryta is formed, and this salt decomposed by carbonic acid, and the carbonate of baryta again converted into caustic baryta.

Preservation of Timber Used in Mines, Coal-Pits, and Quarries.—Dr. Dingler.—This lengthy essay contains the results of a series of practical experiments made with various kinds of wood and almost all substances which have been used to impregnate wood for the purposes of preserving it. It appears that wood thoroughly impregnated with a strong brine (solution of common salt) keeps very well underground.

Relative Goodness and Durability of Timber Felled in Winter or in Summer.—M. Burckhardt.—This subject has never been very much investigated, and the author states, therefore, that very possibly this question cannot be answered. He is inclined to the belief that if trees felled in summer are shelled (the bark stripped off), immediately after having been cut down, the timber thus obtained is in no ways inferior to that obtained from trees cut down in winter.

Journal für Praktische Chemie, No. 17, 1871.

The following original papers are published in this number:—

On Uramidobenzoic Acid Ethyl-Ether and Carboxamidobenzoic Acid Ethyl-Ether.—P. Griess.—After referring to some researches made about three years ago on uramidobenzoic acid, urea, and carboxamidobenzoic acid, the author describes the following bodies:—Ether of uramidobenzoic acid, $C_{15}H_{17}N_2O_5$, C_2H_5 , a solid body, difficultly soluble in water, fuses at 176° ; carboxamidobenzoic acid ether—

a solid crystalline body, insoluble in water, readily soluble in warm alcohol and ether, fuses at 162° , decomposed by boiling alcoholic caustic potassa solution into alcohol and carboxamidobenzoic acid.

Origin and Properties of Monochlorcitramalic Acid.—Dr. J. Gottlieb.—This exhaustive and very lengthy memoir contains the following sections:—Preparation of monochlorcitramalic acid; hydrate of monochlorcitramalic acid, silver, baryta, and lead salts of this acid, $C_6H_7ClO_5$.

Rational Composition of Chlorcitramalic Acid.—H. Kolbe.—Notwithstanding the high scientific value of this paper, its contents are not suited for useful abstraction, on account of the fact that the value of this paper rests entirely upon a series of very lengthy and complicated formulae. The author incidentally observes that citraconic acid should not be treated with liquid hyponitric acid; the author while doing this, in the expectation of thus obtaining dinitropropyrotartaric acid, witnessed the most violent explosion which, to his knowledge, could occur in a chemical laboratory; although the quantity of material was only small, the effects were of a most serious nature, though fortunately nobody was hurt.

On some of the Nitrogen Compounds of Anthrachinon.—R. Beettger and T. Petersen.—The first instalment of a lengthy essay on this subject, divided into the following sections:—a dinitro-anthrachinon, $C_{14}H_6(NO_2)_2O_2$; a diamido-anthrachinon, $C_{14}H_6(NH_2)_2O_2$;

behaviour of a diamido-anthrachinon with nitric acid; behaviour of a dinitro-anthrachinon with concentrated sulphuric acid.

Les Mondes, November 23, 1871.

Experiments in the Mont Cenis Tunnel.—Rev. A. Secchi, S.J., accompanied by Dr. Diamilla-Müller and the Rev. Denza, S.J.—The eminent savants just named have paid a visit to the tunnel alluded to with the view of inspecting that work, wherein already exists a large room hewn laterally out of the rock, to ascertain how far it will be possible to make a series of experiments (pendulum for gravity, magnetic, on the temperature of the rock, &c.) in the tunnel, as well as on the mountains through which it is bored. The experimenting party have already ascertained that the passage of railway trains through the tunnel does not perceptibly affect the accuracy of the experiments intended to be made, and of which a full and complete programme will be drawn up during this winter and all necessary arrangements made for execution next summer. The railway companies have promised every assistance in this work, the preliminaries of which will be made at Rome during this winter.

New Process of Panification.—Dr. Sézille.—The wheat is first deprived of its episperrum (outer cover, or husk) by means of properly constructed machinery; the decorticated grain is next several times added upon by tepid water (about 80° for the first bath and 40° for the subsequent ones), whereby the gummo-resinous cover of the grain is dissolved and removed. This removal is necessary on account of the fact that this substance becomes very deep brown, almost blackish, coloured by fermentation of the dough; the grain at the same time absorbs from 65 to 70 per cent of water, and is then reduced to a paste by means of machinery very similar to that used in chocolate mills. This perfectly white paste is next leavened, and after fermentation ready for baking. By this process, from the same quantity of grain,

which by the usual process only yields 108 to 110 kilos. of bread, the yield is increased to 145 kilos. of very superior quality and far greater nutritive power; moreover, a very considerable saving of labour and expenses connected therewith is effected by the application of this new process, which has been thoroughly tested by competent and independent scientific as well as practical men.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
November 16, 1871.

Toepler's Electrical Machine.—Dr. Albertier.—The detailed description, accompanied by woodcuts, of a peculiar and greatly improved electrical machine (friction) whereby the machine charges itself with negative electricity.

Continuation of the Chemical Researches on Nutritive Substances.—C. Mène.—This portion of the essay treats on the action of the saliva in the digestion.

Bibliography.—Under this heading we meet here with a brief review of "Éléments de Chimie Organique," par M. le Dr. Sacc, Professor of Chemistry at the University of Neuchâtel, published at Paris by Lacroix. This work, specially intended for students who commence to learn organic chemistry, is highly spoken of on account of the clear style and excellent classification of the subject.

Zeitschrift für Chemie von Beilstein, No. 11, 1871.

This number contains the following original papers:—

Chlorhydrates of Hydroxylamin.—W. Lossen.—In addition to the monochlorhydrate of hydroxylamin, $\text{NH}_2\text{O.HCl}$, there have been discovered by the author a semichlorhydrate, $2\text{NH}_2\text{O.HCl}$, and sesquichlorhydrate of the base just named, $3\text{NH}_2\text{O.2HCl}$. The former of these two bodies is prepared by adding to the monochlorhydrate of hydroxylamin in concentrated aqueous solution an equivalent quantity of hydroxylamin in absolute alcohol; while the sesquichlorhydrate is prepared by mixing the mono- and semi-chlorhydrate, and dissolving them in the smallest possible quantity of tepid water. The new salt crystallises from this solution. The two new salts are deliquescent, very soluble in water and weak alcohol, hardly so in absolute alcohol, and insoluble in ether. The semichlorhydrate fuses at 85° , the sesquichlorhydrate at 95° . The reactions exhibited by these substances correspond very closely to those of hydroxylamin.

On an Isomeric Chloro-Nitro-Phenol.—A. Faust.—The author describes briefly the following substances obtained by a complicated process from dinitro-chlorophenol, first converted into amido and then into diazo compounds:—Hydrochlorate β amido-nitro-chlorophenol, $\text{C}_6\text{H}_3\text{ClNH}_2\text{NO}_2\text{O.HCl}$, a yellow-coloured crystalline body soluble in water. Sulphate amido-nitro-chlorophenol—

also crystalline and readily soluble in water; the baryta salt of this compound, $(\text{C}_6\text{H}_3\text{ClNH}_2\text{NO}_2\text{O})_2\text{Ba}+4\text{H}_2\text{O}$, is a crystalline substance, and its aqueous solution exhibits a deep brown colour. β chloronitro-phenol, $\text{C}_6\text{H}_4\text{ClNO}_2\text{O}$, is crystalline, soluble in water, ether, alcohol, and chloroform, and fuses at 112° ; its potassa salt, $\text{C}_6\text{H}_3\text{ClNO}_2\text{O.K}+\text{H}_2\text{O}$, is a brown-coloured crystalline salt soluble in water. Hydrochlorate of amido-chlorophenol, $\text{C}_6\text{H}_4\text{ClNH}_2\text{O.HCl}$, obtained from β chloronitro-phenol by reduction with tin and hydrochloric acid and removal of tin by sulphuretted hydrogen—

a yellow-coloured crystalline substance soluble in water.

Frangulic Acid, a Derivative from Anthracen.—A. Faust.—By treating frangulic acid, $\text{C}_{11}\text{H}_{10}\text{O}_4+\text{H}_2\text{O}$, with zinc-dust at a high temperature anthracen was obtained; and consequently the author states that he is now busy with experiments to ascertain whether the formula of the acid just alluded to should be—

Journal für Gasbeleuchtung und Wasserversorgung, No. 20, 1871.

This number does not contain any original papers other than those relating to gas- and water-works' management and engineering, and we call attention to the—

Gas-Meter Testing Regulations of the North German Confederation, and Instruction to the Gas-Meter Inspectors.—Evidently arranged with very great care and extensive scientific, as well as sound practical, knowledge on this subject.

Annalen der Chemie und Pharmacie, October, 1871.

This number contains the following original papers and memoirs:—

Dissociation and Restoration (Rückbildung) of Carbamate of Ammonium.—A. Naumann.—This exhaustive memoir, elucidated by a series of tabulated forms, contains the following sections:—Introductory observations; experimental proof of the non-volatility of carbamate of ammonium in undecomposed state; density of the gases derived from carbamate of ammonium; mode of experimenting on, observing, and of making the required corrections in phenomena attending the dissociation of carbamate of ammonium; dissociation and rapidity of re-construction of carbamate of ammonium at the ordinary temperature, at 34° , 42° , 46° , and at 20° ; rapidity of dissociation of carbamate of ammonium at $-3^\circ 8'$.

Combinations of Oxide of Bismuth with Sulphuric Acid.—A. Leist.—After first referring to the researches of Dr. Helntz made twenty-seven years ago, and published in *Pogg. Ann.*, vol. lxiii., p. 77,

and the researches lately made by Dr. Schultz-Sellack on this subject, the author describes at length the mode of preparation and properties of the following compounds of oxide of bismuth and sulphuric acid:— $\text{Bi}_2\text{O}_3+4\text{SO}_3+9\text{H}_2\text{O}$, in 100 parts—Oxide of bismuth, 49.05; sulphuric acid, 33.83; water driven off at 110° , 12.420; water driven off at red heat, 6.387. $4\text{Bi}_2\text{O}_3+3\text{SO}_3+15\text{H}_2\text{O}$, in 100 parts—Oxide of bismuth, 78.040; sulphuric acid, 9.80; water at 110° , 3.539; water at red heat, 3.621. $\text{Bi}_2\text{O}_3+2\text{SO}_3+2\text{H}_2\text{O}$, in 100 parts—Oxide of bismuth, 69.043; sulphuric acid, 25.499; water at 110° , 4.291; water at red heat, 1.187.

Diethyliden-Lactamidic Acid.—Dr. W. Helntz.—By a rather complicated and not very clearly described process, the author first prepares diethyliden-lactamidate of copper, which, having been treated with hydrosulphuric acid, yields diethyliden-lactamidic acid, which is obtained from its aqueous solution in small-sized needle-shaped crystals, soluble in dilute but not in absolute alcohol. The crystals are anhydrous, and consist of $\text{C}_6\text{H}_{11}\text{NO}_4$; the formula of the copper salt is $\text{C}_6\text{H}_9\text{CuNO}_4$.

Behaviour of Starch and Dextrine towards Iodine and Tannic Acid.—V. Grissmayer.—The contents of this lengthy essay record a series of experiments made with the view to elucidate the reactions of the bodies alluded to.

Derivatives from Phthalic Acid.—A. Faust.—This exhaustive essay is divided into the following sections:—Introduction; nitro-phthalic acid and its salts; amido-benzoic acid from nitro-phthalic acid; bromo-phthalic acid and salts; dichloro-phthalic acid and salts.

Derivatives from Naphthaline.—A. Faust and E. Saame.—This memoir contains two main sections, viz., the description of the products of addition to naphthaline, and that of the substitution-products of naphthaline; but, notwithstanding the high scientific value of this, as well as of the foregoing memoir, it is not well suited for useful abstraction, an observation also applying to the following exhaustive and very lengthy memoir.

Origin and Properties of Monochlor-Citramalic Acid.—J. Gntlicb.—Introduction; monochlor-citramalic acid hydrate; salts of monochlor-citramalic acid.

NOTES AND QUERIES.

Coagulation of Clay.—Can any of your readers refer me to information respecting the coagulation of clayey water by the addition of salts or other ingredients. It is well known that alum will do this, but I want to know if experiments are on record tried with other substances?—X. Y. Z.

Twaddell and Beaumé.—In answer to J. W.'s query to obtain the sp. gr. of a liquid by Twaddell's hydrometer, multiply the number of degrees by 5 and add 1000 to the product; for instance—

$$115 \times 5 = 575 + 1000 = 1575 \text{ sp. gr.}$$

Exact specific gravities can only be determined by weighing.—H. D. YARLEY.

Specific Gravity.—(Reply to J. W.)—The degrees of Twaddell are easily turned into sp. gr. numbers, a quality which makes it preferable to any other hydrometer in use. The rule is to multiply the indicated degree by 5 and add 1000 to the product; for example, 9° Tw. = $9 \times 5 = 45 + 1000 = 1045$ sp. gr. To bring specific gravities to degrees of Twaddell, subtract 1000 and divide the remainder by 5; for example, 1.125 sp. gr. = 25° Tw. An instrument so much in use should be correct in its indications, but there are very erroneous ones offered for sale, and purchasers should only trust to an instrument made by some well-known and established house.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 4th.—London Institution, 4. Prof. Huxley, LL.D., F.R.S., on "The Physiology of Bodily Motion and Consciousness" (VI.).
— Medical, 8.
— Royal Institution, 2. General Monthly Meeting.
— Anthropological, 8.
TUESDAY, 5th.—Civil Engineers, 8.
— Zoological, 9.
WEDNESDAY, 6th.—Society of Arts, 8.
— Geological, 8.
— Microscopical, 8.
— Pharmaceutical, 8.
THURSDAY, 7th.—London Institution, 7.30. Paper and Discussion, Chemical, 8. Dr. Gladstone, "On Essential Oils."
— Royal, 8.30.
— Royal Society Club, 6.
FRIDAY, 8th.—Astronomical, 8.
— Quekett Microscopical Club, 8.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the *CHEMICAL NEWS* from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

ROYAL INSTITUTION OF GREAT BRITAIN, ALBEMARLE STREET, PICCADILLY, W.

LECTURE ARRANGEMENTS FOR 1871-72.

Subscribers of Two Guineas are admitted to all the Courses. A Single Course, One Guinea or Half-a-Guinea.

LECTURE HOUR, THREE O'CLOCK.

CHRISTMAS LECTURES (adapted to a Juvenile Auditory).

PROFESSOR TYNDALL, LL.D., F.R.S. Six Lectures. "On Ice, Water, Vapour, and Air." On December 28th and 30th, 1871; January 2nd, 4th, 6th, and 9th, 1872.

BEFORE EASTER, 1872.

Dr. W. RUTHERFORD, F.R.S.E. Ten Lectures. "On the Nervous and Circulatory Systems." On Tuesdays, January 16th to March 19th.

PROFESSOR ODLING, F.R.S. Ten Lectures. "On the Chemistry of Alkalies and Alkali Manufacture." On Thursdays, January 18th to March 21st.

W. G. DONNE, Esq. Six Lectures. "On Literature." On Saturdays, January 20th to February 24th.

MONCURE D. CONWAY, Esq. Four Lectures. "On Demonology." On Saturdays, March 2nd to 23rd.

The Friday Evening Meetings will commence on January 13th.

The Friday Evening Discourses before Easter will probably be given by Mr. W. R. Grove, Q.C., the Archbishop of Westminster, Professors Odling and Humphry, Dr. Gladstone, Messrs. C. W. Siemens, R. Liebreich, and John Evans, and Professor Tyndall.

To the Friday Evening Meetings Members and their Friends only are admitted.

AFTER EASTER.

Dr. WILLIAM A. GUY, F.R.S. Three Lectures. "On Statistics, Social Science, and Political Economy." On Tuesdays, April 9th, 16th, and 23rd.

EDWARD B. TYLOR, Esq., F.R.S. Six Lectures. "On the Development of Belief and Custom amongst the Lower Races of Mankind." On Tuesdays, April 30th to June 4th.

PROFESSOR TYNDALL, LL.D., F.R.S. Nine Lectures. On Thursdays, April 11th to June 6th.

R. A. PROCTOR, Esq., B.A., F.R.A.S. Five Lectures. "On Star Depths." On Saturdays, April 13th to May 11th.

PROFESSOR ROSCOE, F.R.S. Four Lectures. "On the Chemical Action of Light." On Saturdays, May 18th to June 8th.

To Non-Members, the admission to all these Courses of Lectures is Two Guineas; to a Single Course of Lectures, One Guinea or Half-a-Guinea, according to the length of the Course.

Gentlemen desirous of becoming Members are requested to apply to the Secretary.

New Members can be proposed at any Monthly Meeting. When proposed, they are admitted to all the Lectures, to the Friday Evening Meetings, and to the Library and Reading Rooms; and their Families are admitted to the Lectures at a reduced charge. Payment:—First year, Ten Guineas; afterwards, Five Guineas a year; or a composition of Sixty Guineas.

Prospectuses (when prepared) may be had in the hall.

H. BENCE JONES, Hon. Sec.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Part 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND Co., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE OF CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c.: of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 4, Berners-street, W.

ANALYTICAL LABORATORY and SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied and the erection of Plant and Buildings is superintended when required.

New Laboratory Apparatus:—

CENTRE BLAST BUNSEN, combining a Bunsen, and a very powerful Herapath, 10s. 6d.

HOT-BLAST BLOWPIPE, giving the temperature exceeding the fusing-point of platinum, 9s. 6d.

TABLE FURNACE, without blast, for operations below a white heat, 30s.

The above were awarded the first medal of the Royal Cornwall Polytechnic Society, 1871. Drawings, &c., one stamp.

T. FLETCHER, 15, BOLD ST., WARRINGTON.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA OF HONOUR, being the First Prize, and superior to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar Sold by all Italian Warehousemen, Grocers, Chemists, and Ships, Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, MARK LANE, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British French, Prussian, Russian' and other Governments.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

CONTRIBUTIONS TO THE HISTORY OF THE OPIUM ALKALOIDS.*

By C. R. A. WRIGHT, D.Sc.,
Lecturer on Chemistry in St. Mary's Hospital Medical School.
(Concluded from p. 257).

3. Action of Sodium Carbonate on the Compound $C_{68}H_{86}I_2N_4O_{12.4}HI$.

On adding sodium carbonate to the scarcely warm aqueous solution of this compound a voluminous white precipitate is produced, which is apparently a mixture of three bases, two of which contain iodine, whilst the third is free from that ingredient. The first one, which forms only a small fraction of the whole, is the free base of the original compound, $C_{68}H_{86}I_2N_4O_{12}$; this is readily soluble in ether, and may be obtained as hydriodate (as previously stated) by digesting the precipitate with ether, and agitation of the extract with hydriodic acid, whereby the original substance is reproduced. To prevent frothing, the precipitate must be well drained from the aqueous portion. By continuing the extraction until some 6 litres of ether have been employed for exhausting the precipitate from 40 grms. of original substance, the whole of this base is removed, or nearly so. Attempts to prepare the base itself by evaporation of the ether yielded only a tarry substance which could not be removed from the vessel employed; treatment with water or alcohol more or less decomposes it.

By employing a large bulk of ether after this first base has been almost wholly removed, an extract is obtained from which on evaporation solid flakes separate; these are much less soluble in ether than the first base, and after drying at 100° gave the following numbers, indicating the formula $C_{68}H_{81}IN_4O_{10}$.

0.1985 grm. gave 0.4705 CO_2 and 0.119 H_2O .
0.1210 grm. gave 0.2600 AgI.

	Calculated.		Found.
C_{68}	816	65.81	64.65
H_{81}	81	6.53	6.66
I	127	10.24	11.61
N_4	56	4.52	
O_{10}	160	12.90	
$C_{68}H_{81}IN_4O_{10}$	1240	100.00	

Apparently these flakes still retained a trace of the first base; the mother-liquor from which they separated, when evaporated to dryness, left a small amount of residue containing 14.18 per cent of iodine. Treated with hydriodic acid, these flakes gave a hydriodate yielding these numbers after drying at 100° :-

0.3675 grm. gave 0.6335 CO_2 and 0.181 H_2O .
0.371 grm. gave 0.2405 AgI.

	Calculated.		Found.
C_{68}	816	46.58	47.00
H_{85}	85	4.85	5.47
I_5	635	36.24	35.02
N_4	56	3.20	
O_{10}	160	9.13	
$C_{68}H_{81}IN_4O_{10.4}HI$	1752	100.00	

Evidently a slight loss of iodine has occurred from the action of the adhering moisture while drying, as the original flakes contained rather too high a percentage of iodine. This base is formed from the original one by the reaction—

identical with that taking place on treatment with water.

A portion of the substance left after extraction with ether was treated several times successively with large bulks of ether (about 4 litres of ether to 10 grms. of precipitate each extraction). After the majority of the substance had thus been dissolved, a portion of the last ether extracts was evaporated down and yielded flakes agreeing approximately with the composition required for a mixture of 1 molecule of $C_{68}H_{81}IN_4O_{10}$, and 2 molecules of $C_{68}H_{80}N_4O_{10}$.

0.3565 grm. gave 0.926 CO_2 and 0.237 H_2O .
0.376 grm. gave 0.255 AgI.
0.2455 grm. gave 0.170 AgI.

	Calculated.		Found.
C	70	67	70.84
H	6	95	7.39
I	3	67	3.66 3.73

From the foregoing experiments it is clear that the action of sodium carbonate on the compound

is identical with that of water described in (2), the two bases, $C_{68}H_{81}IN_4O_{10}$ and $C_{68}H_{80}N_4O_{10}$, being the principal products.

On precipitating in a similar way the compound

the same reaction appears to take place; from the precipitate ether extracts only traces at first, indicating probably that the base $C_{68}H_{81}I_2N_4O_{10}$ is not produced in any quantity; as apparently the more highly iodised bases are more soluble in ether.

On treating the compound $C_{68}H_{81}I_2N_4O_{10.4}HI$ in the same way, an analogous reaction seems to ensue; the precipitate is very sparingly soluble in ether, and on treatment with hydriodic acid furnished a hydriodate of which 0.233 grm. dried at 100° gave 0.142 AgI; hence $I = 29.94$ per cent; the compound $C_{68}H_{88}N_2O_{10.4}HI$ requires 31.13 per cent, whilst the original substance requires 40.53 per cent.

4. Action of Hydriodic Acid on some of the foregoing substances.

As the action of water on the three compounds first described is to remove the elements of HI associated with the carbon radicals of the bases, it was thought probable that by treating the products of the action of water on these compounds with strong boiling hydriodic acid, the HI thus lost might be again added on. A reaction of this nature does indeed take place, but does not always stop at the reproduction of the original bodies, another equivalent of HI being also added on; moreover, in some instances a number of molecules of H_2O are likewise taken up, and are not separated from the compounds ultimately formed even by some days' exposure to a temperature of 100° .

On treating the compound $C_{68}H_{80}N_4O_{10.4}HI$ with about ten parts of 55 per cent of hydriodic acid (a little piece of phosphorus being also added to prevent separation of iodine from the HI by the heat) and heating to boiling, a syrupy liquid is obtained, from which water precipitates (after filtration of phosphorus) a tar resembling in all its physical characters the compound $C_{68}H_{86}I_2N_4O_{12.4}HI$; it contains, however, the elements of $HI + 10H_2O$ more than this substance. The same substance apparently is generated by treating the intermediate compound

with hydriodic acid in the same manner.

* Read before the Royal Society, November 16, 1871.

(A.) From the compound $C_{68}H_{80}N_4O_{10.4}HI$; dried at 100° till constant:

0.3565 grm. gave 0.483 CO_2 and 0.158 H_2O .
0.3835 grm. gave 0.278 AgI.

(B.) (A) dried twelve hours more at 100° , had turned a much darker colour, probably indicating absorption of oxygen:

0.329 grm. gave 0.434 CO_2 and 0.155 H_2O .
0.561 grm. gave 0.419 AgI.

(C.) From the compound $C_{68}H_{81}N_4O_{10.4}HI$:

0.377 grm. gave 0.485 CO_2 and 0.175 H_2O .
0.387 grm. gave 0.285 AgI.

	Calculated.		Found.			Mean.
	A.	B.	C.			
C_{68}	816	36.69	36.95	35.98	35.09	36.01
H_{111}	111	4.98	4.93	5.24	5.16	5.11
I_7	889	39.98	39.16	40.35	39.87	39.79
N_4	56	2.52				
O_{22}	352	15.83				

2224 100.00

$C_{68}H_{107}I_3N_4O_{22.4}HI$.

Hence this body is formed by the equations—

On treating the compound $C_{68}H_{83}N_4O_{10.4}HI$ in the same way a product is obtained only differing from the original substance by one equivalent of HI; dried at 100° :

0.3995 grm. gave 0.6800 CO_2 and 0.197 H_2O .
0.3215 grm. gave 0.2200 AgI.

	Calculated.		Found.
C_{68}	816	46.36	46.41
H_{93}	93	5.28	5.48
I_5	635	36.09	36.97
N_4	56	3.18	
O_{10}	160	9.09	

$C_{68}H_{89}N_4O_{10.4}HI$ 1760 100.00

Hence this body appears to have been formed by the reaction $C_{68}H_{88}N_4O_{10.4}HI + HI = C_{68}H_{89}N_4O_{10.4}HI$, no water having been taken up; whilst in the case of the other non-ionised base, 3 molecules of HI and 12 of H_2O are assimilated.

In order to see if the combined action of phosphorus and hydriodic acid would transform the compound

into the body $C_{68}H_{82}I_2N_4O_{6.4}HI$, the former compound was dissolved in about 10 parts of 55 per cent hydriodic acid, and boiled until most of the acid had volatilised; a considerable quantity of phosphoric acid was formed during the reaction, and on precipitating the compound produced with water, and drying at 100° , the following numbers were obtained:—

0.2795 grm. gave 0.3900 CO_2 and 0.136 H_2O .
0.4195 grm. gave 0.327 AgI.
0.4225 grm. gave 0.333 AgI.

	Calculated.		Found.
C_{68}	816	38.42	38.06
H_{107}	107	5.04	5.41
I_7	889	41.85	42.12
N_4	56	2.64	
O_{16}	256	12.05	

$C_{68}H_{103}I_3N_4O_{16.4}HI$ 2124 100.00

From these numbers it appears that the substance produced may be considered as formed by the reactions,

It is not easy to explain why the reaction should stop short at the end of the first stage, when codeia is treated with hydriodic acid and boiled up to 130° ; possibly the presence of a much larger quantity of phosphorus acids in this case may tend to prevent the second reaction ensuing.

5. Discussion of the Foregoing Results.

From the complex constitution of the substances described above, it is at present thought unadvisable to attempt to give names to them. All the bodies previously mentioned may be regarded as being derived from one or other of the two bases $C_{17}H_{21}NO_3$ and $C_{17}H_{21}NO_2$ by multiplication of the molecule, and addition or subtraction of the elements of water and of hydriodic acid.

These two (hypothetical) bases contain H_2 more than morphia and deoxymorphia respectively; denoting the first by the symbol X, and the second by Y, the following general formulæ will indicate all the compounds previously described:—

Thus the following table illustrates the mutual relations of the compounds described:—

Source of Compound.	Formulæ.
(A) Codeia, HI, and P at 150°	$C_{68}H_{86}I_2N_4O_{12.4}HI = 4X + 6HI$
(B) Do. 110° to 115°	$C_{68}H_{82}I_2N_4O_{10.4}HI = 4X + 6III - 2H_2O$
(C) (A) treated with water or Na_2CO_3	$C_{68}H_{81}IN_4O_{10.4}HI = 4X + 5III - 2H_2O$
(D) Free base of (C), (A) treated with Na_2CO_3	$C_{68}H_{81}IN_4O_{10.4}HI = 4X + HI - 2H_2O$
(E) Further action of water on (C)	$C_{68}H_{80}N_4O_{10.4}HI = 4X + 4III - 2H_2O$
(F) Action of HI on (E)	$C_{68}H_{107}I_3N_4O_{22.4}HI = 4X + 7III + 10H_2O$
(G) Codeia, HI, and P at 135°	$C_{68}H_{82}I_2N_4O_{6.4}HI = 4Y + 6III - 2H_2O$
(H) Action of water on (G)	$C_{68}H_{88}N_4O_{10.4}HI = 4Y + 4III + 2H_2O$
(I) Action of III on (H)	$C_{68}H_{89}IN_4O_{10.4}HI = 4Y + 5III + 2H_2O$
(J) Action of III on (A)	$C_{68}H_{103}I_3N_4O_{16.4}HI = 4Y + 7III + 8H_2O$

Although it may well happen that further researches may show that some of the above formulæ require some slight correction, the analytical numbers not always agreeing together absolutely accurately, yet the following points may be considered established:—

(1). The action of hydriodic acid on codeia polymerises it, the ultimate compounds formed being derived from at least four molecules of codeia. Hydrobromic acid also polymerises codeia, but not so completely as hydriodic acid, there being found, in addition to the tetra-bases, compounds which (from their crystalline character and other physical properties) are apparently derived from 1 molecule only of codeia. Hydrochloric acid does not appear to have a marked polymerising effect on codeia.

(2). Hydriodic, hydrobromic, and hydrochloric acids all eliminate methyl from codeia, forming ultimately compounds containing nC_7 .

(3). The compounds got by the action of hydriodic acid in presence of phosphorus indicate that the carbon groups contained in codeia are in an eminently "unsaturated" condition, being capable of taking up several molecules of HI and of H_2O , forming compounds not decomposed at 100° ; 2 equivalents of hydrogen for every C_{17} being also added on in every case.

ASSAY FOR GOLD AND SILVER.

By T. M. BLOSSOM, E. M.

(Continued from p. 44).

4. *Weighing the Bead.*—The bead of gold and silver is detached from the cupel with pincers, thoroughly cleansed, and weighed. The balance used for this purpose is exceedingly delicate, it being possible to read with it down to tenths of a milligramme.

5. *Inquartation and Parting.*—The separation of gold from silver is termed *parting*. It is effected, generally, by means of nitric acid, which dissolves the silver and leaves the gold, in the assay of ores, in a loosely adherent spongy mass, or a dull powder. It is essential that a certain relation should exist between the amount of gold in the alloy and that of the silver. If there be too little silver present, it will not be dissolved completely, but a part of it will be so enveloped in the gold as to escape the action of the strongest acid. If, on the other hand, too much silver be present, the gold is too highly diluted, and is obtained in leaves so fine and light as to occasion a loss in the subsequent washing. The silver should be from 2.5 to 3 times the amount of gold. The assayer must judge by the colour of the bead as to the proportion of silver contained; and if it be too small he must supply the deficiency with pure silver. In assaying ores, no attempt is made at an adjustment when the silver is in excess, but great care is necessary in the parting. This is a matter of more importance in bullion assay. This adjustment of the proportion of silver is called "Inquartation" or "Quartation," and will be treated more fully under "Assay of Alloys." Silver is kept on hand in thin foil, from which little bits can easily be cut with pliers. The bead and the silver are fused well together, to effect complete distribution of the silver. The fusion is made most conveniently on charcoal by means of the blowpipe, if a few beads only are being treated. If a large number are to be treated, it may save time to wrap the bead and silver in a corner of lead-foil and cupel it, since several can be fused at the same time. The inquartated bead is flattened on the anvil and treated in a porcelain capsule with pure nitric acid of 1.16 sp. gr. Enough acid is added to cover the bead completely. Heat gently, taking care not to boil violently and scatter the gold. It is to prevent the occurrence of the latter that we do not employ at first a very strong acid, which might create too brisk an action and break up the gold. The acid must be free from chlorine, which would precipitate the silver. When all action of the first acid has ceased, it is decanted gently, and some fresh acid of 1.26 sp. gr. is added. Heat for several minutes, then pour off the acid, wash thoroughly with distilled water and dry the residue of gold. It is well to apply a high heat before attempting to remove the gold, for the spongy mass is thus rendered adherent and may be removed without crumbling. The gold residue is now detached with a knife, transferred to a corner of lead, and cupelled.

6. *Weighing the Gold Bead.*—The gold bead obtained from the last cupellation is weighed, and the assay is completed. It remains only to calculate the results.

Calculation of Results.

This is a simple operation and hardly needs explanation. As already stated, the milligrammes of precious metal obtained per assay ton of ore correspond to ounces in the ton of 2000 lbs. av. Let us take, however, the special example of an ore containing metallic gold or silver finely disseminated throughout the ore, and occurring in scales which remain upon the sieve. This will embrace and suggest all cases likely to arise in ordinary practice. It may be necessary to state here, that the treatment of the scales consists only of a cupellation, or of scorification and

cupellation combined, according to the nature of the material (Assay of Alloys).

Let us suppose that the sample presented for assay gave, on being pulverised and passed through a sieve of 80 meshes to the linear inch, the following weights:—

A. Sifted ore	1458.32 grms.
B. Scales of metal	40.75 "
C. Total	1499.07 grms.

It being known from the mineralogical composition of the sample that it was a rich ore, $\frac{1}{8}$ A.T. was taken for an assay of the sifted portion (A). The residue of metallic scales, &c. (B), was scorified with test-lead, and yielded a button weighing 60.35 grms. of the lead alloy. This button was rolled out, and two average samples, of 10 grms. each, were cupelled.

The following results were obtained from the complete assays:—

A. SIFTED ORE.—Crucible Assay.

One-third assay ton, 9.722 grms., yielded:—

	1.	2.	Average.
Au + Ag.	0.19355	0.19275	0.19315
Au (by parting)	0.00025	0.00025	0.00025
Ag.	0.19330	0.19250	0.19280
Ag in litharge*	0.00067	0.00067	0.00067
Ag. in ore	0.19263	0.19183	0.19213

B. METALLIC SCALES.

Ten grms. of the scorified button yielded:—

	1.	2.	Average.
Au + Ag.	5.0625	5.0620	5.0622
Au (by parting)	0.0020	0.0020	0.0020
Ag.	5.0605	5.0630	5.0602
Ag. in test-lead	none	none	none

A. Sifted ore .. 1458.32 $\times \frac{0.19213}{9.722}$ = 28.819 Ag.

B. Metallic scales 40.75 $\times \frac{5.0602}{10} \times 60.35$ = 30.538 Ag.

C. Total ore .. 1499.07 59.357 T^l Ag.

$29166.66 \times \frac{59.357}{1499.07} = 1154.71$ ozs. per 2000 lbs.

A. Sifted ore .. 1458.32 $\times \frac{0.00025}{9.722}$ = 0.0375 Au.

B. Metallic scales 40.75 $\times \frac{0.002}{10} \times 60.35$ = 0.0121 Au.

C. Total ore .. 1499.07 0.0496 T^l Au.

$29166.66 \times \frac{0.0496}{1499.07} = 0.97$ czs. per 2000 lbs.

RESULT PER 2000 LBS. ORE.

	Ozs.	Dols.	Dols.
Silver	1154.71 at 1.29 ..	1489.58	
Gold	0.97 at 20.67 ..	20.04	

Total bullion 1155.97 1509.62

GALENA.—*Special Method.*—It is best and most convenient always to make a scorification assay of galena. If, however, it be desirable for any reason to make a crucible assay, a charge of nitre and carbonate of soda is

* The litharge yielded 1 milligram. silver per assay ton, and two-thirds assay ton were employed.

generally employed instead of roasting the ore. Twenty grms. of nitre per assay ton of ore are required for pure galena; this amount diminishing, of course as the gangue increases in quantity, or the amount of sulphur is lessened. Employ the same weight of carbonate of soda as of ore. If there be any doubt as to the amount of nitre required, make a preliminary assay with an assumed charge, and modify the regular charge according to the result.

Concluding Remarks concerning the Assay of Ores.

Any of the substances mentioned under the head of "Ores and Minerals" can be assayed by either the foregoing methods (a) Crucible and (b) Scorification. There is only one practical limit in the case of scorification involved, as before mentioned, in the richness of the ore. The latter method is preferable whenever it can be used conveniently. It yields higher results and requires no preliminary assay. There is a roasting period in the operation, but it is simple, and is free from many of the disagreeable features of a preliminary roasting. No oxy-sulphurets are formed, or, if formed, are decomposed during the operation; whereas, in the crucible assay, they may escape decomposition, even at a white-heat. It is a better method for very rich copper ores; the action of scorification is oxidising, that of the crucible reducing; hence, in the latter case, much copper will enter the lead-button that, in the former case, would be oxidised and enter the slag.

NOTE ON THE SPECTRUM OF THE AURORA.

By G. F. BARKER.

On the evening of November 9th, there appeared one of the most magnificent crimson auroras ever seen at this place. When first observed, at about a quarter before six, p.m., it consisted of a brilliant streamer shooting up from the north-western horizon; this was continued in a brilliant red, but rather nebulous, mass of light, passing upward and to the north. Its highest points were from 30° to 40° in altitude. A white aurora, consisting of bright streamers, appeared simultaneously, and extended round to the north-east.*

The crimson aurora was examined with a spectroscope at six o'clock. The instrument used was a single glass-prism spectroscope, made by Duboseq, of Paris. On directing the slit towards the brilliant streamer above mentioned, a bright spectrum was observed, consisting of five well-marked lines. A millimetre scale attached to the instrument was then illuminated with a gas-flame, the auroral lines being readily measured, even when the numbers on the scale were bright enough to be read distinctly. The sodium line was used to adjust the scale, being equally divided by the division 100; the width of the slit was about one millimetre. As thus arranged, the five auroral lines, beginning at the red end, had the following positions:—Scale-Nos. 90, 110.5, 130, 138, 149. The brightness of the lines was, following the above order, 3, 1, 5, 2, 4, the second line from the red end of the spectrum being the brightest. The line marked 90 and the one marked 110.5 were sharp and well-defined; the others were all nebulous on the edges.

Before the measurements were completely verified by a second comparison, the crimson aurora entirely vanished, leaving endured less than a half hour. In the white

* Professor Newton informs me that he observed an equally brilliant red patch of auroral light in the north-east, five or ten minutes earlier. Since the lower end of the red streamers was much lower than that of the white, it would seem as if the red were seen through the white, the red being most remote.

aurora which remained, the spectroscope showed four of the five lines given; the crimson line alone was absent. The measurements are exact to half a division of the scale.

To determine the approximate wave-length of these lines comparison was made both with certain metallic lines and with the lines of the solar spectrum. On the scale of this instrument, the metallic lines employed read as follows:—

Ka 63, Lia 79, Srβ 80, H(c) 82, Caa 91, Sra 96, Caβ 113, 11(f) 146.5, Srδ 163, Csβ 165, Csa 167, Rba and β 200, Kβ 218.

The Fraunhofer lines measured as follows:—

a 70.5, B 76, C 82, D 100, E 124.5, b 130, F 146.5, G 189.

Direct interpolation was used in comparing the wave-length of the auroral lines with those given above, the wave-lengths of the Fraunhofer and elemental lines being taken from Gibbs's tables (*Am. Journ. Sci.*, II., xliii., 1; xlvii., 194). This method was believed capable of giving results as close as the instrumental measurements. In this way the wave-lengths of the five auroral lines were obtained as given in the following table:—

Line.	Scale number.	Wave-length.	Auroral lines.	Other measurements.
B	76.0	687		
C	82.0	656		
(1)	90.0	623	623	627 Zöllner.
D	100.0	589		
(2)	110.5	562	562	556 Angström.
E	124.5	527		
(3)	130.0	517	517	520 Winlock.
b	130.0	517		
(4)	138.0	502	502	
F	146.5	486		
(5)	149.0	482	482	485 Alvan Clark, Jr.
G	189.0	431		

In this table, column 1 gives the auroral and the Fraunhofer lines; column 2, the number of these are measured upon the scale of the spectroscope used; column 3, the wave-lengths of these lines obtained as above stated; column 4, the wave-lengths of the auroral lines, given by themselves; and column 5, the wave-lengths of what I assume to be the same lines, with their wave-lengths as measured by the observers mentioned.

The point of particular interest in this observation is the fact that the line (4) of wave-length 502 is not laid down in any authority accessible to me as having been observed in the auroral spectrum. Indeed, no previous observer, so far as I know, has seen any auroral line between the Fraunhofer lines b and F. Professor C. A. Young (*Am. Journ. Sci.*, III., ii., 332, Nov. 1871) gives two lines—Nos. 56 and 57, or 1866.8 and 1870.3 of Kirchhoff—observed by him in the sun's chromosphere and also by Rayet in the eclipse of 1868, one of which may coincide with this fourth auroral line.—*American Journal of Science.*

New Haven, Nov. 13, 1871.

ON THE EVAPORATION TO DRYNESS OF GELATINOUS PRECIPITATES.

By THOMAS M. CHATARD.

IN a former paper* I called attention to the fact that many gelatinous precipitates, when evaporated to dryness, became very granular and easy to filter. I gave some examples then and have since tested several others.

* *Am. Journ. Sci.*, vol. i., p. 247.

Titanic Acid.—Rutile was fused with sodic disulphate, the titanic acid precipitated by ammoniac hydrate and evaporated to dryness. It became quite sandy and washed with great rapidity and thoroughness.

Glucina.—Pure glucina was dissolved in chlorhydric acid, precipitated by ammoniac hydrate and evaporated to dryness. In this case, as glucina is soluble in ammoniacal salts, it was necessary to ignite the dry mass to expel these. This was done in the platinum dish in which the evaporation was carried on. The residual glucina was sandy and washed with great ease; *zirconic*, *niobic*, and *tantallic acids* when thus treated gave results which were all that could be desired.

Ceric, lanthanic, and didymic oxalates, when treated with sulphuric acid, and ammoniac hydrate added, gave also perfectly satisfactory results.

In conclusion, there seems to be no doubt that almost any gelatinous precipitate can be successfully treated in this manner.—*American Journal of Science.*

HERRESHOFF'S METHOD FOR VALUING BLEACHING-POWDER.

By A. H. MASSEY,
Student at King's College, London.

THE standard solutions were the same in every respect as those described in the *CHEMICAL NEWS* (vol. xxiii., p. 293). The method of preparing the solution of powder consisted in weighing 10 grms. of the sample and triturating in a mortar with water. The solution so obtained was poured into a graduated flask, and filled up to one litre. The clear liquid was drawn off, 100 c.c. were taken, 50 to 100 c.c. of water and 10 c.c. of hydrochloric acid added. A few drops of starch and iodide of potassium prepared the solution for titration with potassic dichromate.

Four samples of the same powder gave the following percentages of available chlorine:—

24.92 per cent.
24.70 "
24.80 "
25.00 "

The author has not found any difficulty in purifying arsenious acid by sublimation, or in preparing solutions of arsenite of soda for volumetric estimations of chlorine.

Three samples of the same powder previously valued by Herreshoff's method gave by Penot's method the following results:—

Active Chlorine.
24.76 per cent.
24.70 "
24.59 "

These numbers show that both processes may be considered equally accurate.

ON THE GASES OCCLUDED IN COAL.

By Dr. E. MEYER.

I DESIRE this paper to be considered only as a preliminary notice, it being my intention to extend these researches. Since, so far as I am acquainted, the question whether any at all, and, if so, what kind of gases are occluded in coal has not been experimentally dealt with, it occurred to me to test Zwickau coals (Saxony) in this respect.

Lumps of hard and compact coal the size of a walnut were put into a flask, previously partly filled with thoroughly well-boiled and hot distilled water, the flask was next

closed with a perforated caoutchouc stopper wherein a glass tube was fitted, which, serving as gas-conveying tube, was carried into a vessel filled with water deprived of air. The apparatus thus arranged was kept at boiling heat for some time in order thereby to eliminate the film of air which mechanically adheres to the coal. The boiling was further continued after the gas-conducting tube had been placed over a graduated glass tube, previously filled with distilled water freed from air and placed on a pneumatic trough. The gas thus collected (constantly evolved from the lumps of coal) was analysed according to Bunsen's method, and found to consist in the first sample operated upon, percentically, of:—Carbonic acid, 16.9; marsh-gas, 20.4; nitrogen, 53.3; oxygen, 1.7; heavy carburetted hydrogens absorbable by fuming sulphuric acid 7.7. Second sample—Carbonic acid, 22.4; marsh-gas, 22.3; nitrogen, 48.0; oxygen, 4.1; heavy carburetted hydrogens absorbable by fuming sulphuric acid. The large quantity of nitrogen and the small quantity of oxygen deserve special notice. The samples of coal experimented with had been kept in a cellar for a period of several months in contact with air so that it would appear that the oxygen of the air absorbed has served for the oxidation of the coal and formation of carbonic acid.

I may not also neglect to call attention to the heavy carburetted hydrogens which, as far as I am aware, have not been hitherto noticed as being occluded in coal. It might be surmised, yet it is very improbable, that these heavy carburetted hydrogens have been formed by the heating of the coal under water at 100°. I intend to elucidate this point by exhausting the gases from coal with the aid of a mercurial air-pump at the ordinary temperature of the air in order to ascertain whether the same kind of coal will then also yield carburetted hydrogens absorbable by fuming sulphuric acid. These researches will be continued and extended to other kinds of coal. The results of my experiments I shall publish at a future date.—*Journal für Praktische Chemie.*

NOTES OF

DEMONSTRATIONS ON PHYSIOLOGICAL CHEMISTRY AT ST. GEORGE'S HOSPITAL.

By S. W. MOORE.

VI.

I PURPOSE here classifying briefly the various data obtained at previous demonstrations, so that they may be applied for clinical purposes or otherwise to the fluids and solids of animal production.

Fluids.

(a). Note whether any solid particles are suspended, and if so, filter; frequently in hydrocele and ovarian cyst fluids, fibrin in flocculi, or plates of cholesterine occur.

(3). Observe the colour; if practicable apply spectroscopic. The most frequent pigments are those of blood and bile; blood may be distinguished by the microscope, and bile by adding HNO_3 , which causes chameleonic changes of colour.

(γ). Take the sp. gr. if possible by some form of hydrometer; many fluids require the sp. gr. bottle for accurate determination. If much fat be present, as in milk, the sp. gr. does not indicate much of importance.

(δ). Evaporate a portion to dryness, and incinerate the residue, testing the ash in the ordinary way or by the spectroscopic.

(ε). Ascertain whether acid or alkaline with test-papers if acid, albuminous bodies will probably be absent; if alkaline, note whether from putrefaction.

(ζ). Add HCl to the fluid; if a precipitate occur, slightly acidulate a portion of the original and boil; a precipitate

indicates albumin. If no precipitate occurs on boiling, add acetic acid; a precipitate indicates casein. If, however, a precipitate did occur in the original fluid on boiling, then filter, and treat the filtrate as above.

(7). Evaporate a portion of the liquid, freed from albuminous matter, to $\frac{1}{10}$ th of its original bulk; if allantoin be present it will separate, as will leucin; add HCl, if hippuric or uric acids be present they will precipitate. Hippuric acid on burning gives off fumes of benzoic acid; uric acid is proved by the murexide test.

(8). Evaporate a portion to dryness, powder, and boil with ether or benzol to remove fat.

Palmitin, stearin, and olein saponify, whilst cholesterin and serolin (?) do not.

(9). Evaporate to $\frac{1}{10}$ th bulk, and add HNO_3 ; if urea be present it separates as nitrate of urea; alcohol takes up urea, bilin, &c.

(10). Proof-spirit takes up sugars, NaCl, &c. The presence of sugar in the spirit extract may be proved by the formation of melassic acid with KHO, also with the copper test.

The application of these principles is exceedingly simple, and, though anything but a delicate system of analysis, will yield very useful results to the inquirer.

A few watch-glasses, some test-tubes, a piece of platinum foil, a urinometer, and some filtering and test-papers, are all the apparatus needed for ordinary work of this kind.

Solids.

These are generally pathological products, but a very similar course may be applied to their analysis, thus:

First incinerate to ascertain if wholly organic, and then boil successively in water, alcohol, spirit, benzol, acid (acetic), and alkali, and to the products apply the test as directed above.

LETTERS FROM M. LAVOISIER TO DR. BLACK.

THROUGH the kindness of Professor Andrews, we are able to publish the letters to which he referred in his address to the Chemical Section of the British Association, October 3rd, 1871. The following passage from Dr. Andrews's address forms a fitting introduction to these letters:—

"Whatever may be the true value of the Stahlian views, there can be no doubt that the discoveries which have shed so bright a lustre round the name of Black mark an epoch in the history of science, and gave a mighty impulse to human progress. A recent attempt to ignore the labours of Black and his great contemporaries, and to attribute the foundation of modern chemistry to Lavoisier alone, has already been amply refuted in an able inaugural address delivered a short time ago from the chair formally occupied by Black. The statements of Dr. Crum Brown may, indeed, be confirmed on the authority of Lavoisier himself. Through the kindness of Dr. Black's representatives, I have been permitted to examine his correspondence, which has been carefully preserved, and I have been so fortunate as to find in it three original letters from Lavoisier to Dr. Black. They were written in 1789 and 1790, and they appear to comprise the whole of the correspondence on the part of Lavoisier which passed between those distinguished men. Some extracts from these letters were published soon after Dr. Black's death by his friends Dr. Adam Ferguson and Dr. Robinson; but the letters themselves, as far as I know, have never appeared in an entire form. I will crave permission to have them printed as an appendix to this address. Lavoisier, it will be seen, addresses Black as one whom he is accustomed to regard as his master, and whose discoveries had produced important revolutions in science. It may, indeed, be said with truth that Lavoisier completed the foundation on which the grand structure of modern chemistry

has since arisen; but Black, Priestley, Scheele, and Cavendish were before Lavoisier, and their claims to a share in the great work are not inferior to those of the illustrious French chemist."

LETTERS FROM M. LAVOISIER TO DR. BLACK.

Paris, le 19 Septembre, 1789.

Monsieur,—C'est un membre de l'Académie Royale des Sciences de Paris qui vous écrit à titre de Confrère: c'est un des plus zélés admirateurs de la profondeur de votre génie et des importantes révolutions que vous découvrez ont occasionnées dans les Sciences, qui profite, pour avoir l'honneur de vous écrire, de l'occasion de M. de Boullogne qui va finir son éducation à Edimbourg. Permettez-moi de vous le recommander. Il joint à d'heureuses dispositions un grand désir de s'instruire et il regarde comme un grand bonheur pour lui d'avoir une occasion pour se présenter à vous. Il a bien voulu, Monsieur, se charger de vous remettre un exemplaire d'un ouvrage que je viens de publier; vous y trouverez une partie des idées dont vous avez jeté le premier germe: si vous avez la bonté de donner quelques instants à sa lecture, vous y trouverez le développement d'une Doctrine nouvelle que je crois plus simple et plus d'accord avec les faits que celle du Phlogistique. Ce n'est au surplus qu'en tremblant que je le soumetts au premier de mes juges et à celui dont j'ambitionnerais le plus le suffrage.—J'ai l'honneur d'être très-respectueusement, Monsieur, Votre très-humble et très-obéissant Serviteur,—LAVOISIER.

Paris, 24 Juillet, 1790

Monsieur,—J'apprends avec une joie inexprimable que vous voulez bien attacher quelque mérite aux idées qui j'ai professé le premier contre la doctrine du phlogistique. Plus confiant dans vos idées que dans les miennes propres, accoutumé à vous regarder comme mon maître, j'étois en défiance contre moi-même tant que je me suis écarté sans votre aveu de la route que vous avez si glorieusement suivie. Votre approbation, Monsieur, dissipe mes inquiétudes et me donne un nouveau courage. Cette Lettre, Monsieur, vous sera remise par M. Terray intendant de Lyon neveu du Ministre des finances de ce même nom et mon parent; il conduit à Edimbourg son fils, jeune homme d'espérance et destiné à posséder une grande fortune; pour y finir son éducation et suivre les leçons des professeurs célèbres de l'université d'Edimbourg. Permettez-moi, Monsieur, de vous le recommander. L'intérêt que vous voudrez bien prendre à lui sera un premier titre qui l'annoncera d'une manière avantageuse et j'ai lieu de croire qu'il ne se rendra pas indigne de vos bontés. Je ne serai pas content jusqu'à ce que les circonstances me permettent de vous aller porter moi-même le témoignage de mon admiration et de me ranger au nombre de vos disciples. La révolution qui s'opère en France devant naturellement rendre inutile une partie de ceux attachés à l'ancienne administration, il est possible que je jouisse de plus de liberté; et le premier usage que j'en ferais sera de voyager et de voyager surtout en Angleterre et à Edimbourg pour vous y voir, pour vous y entendre et profiter de vos lumières et de vos conseils. J'ai commencé un grand nombre d'ouvrages et de travaux et j'aspire à un Etat de tranquillité qui me permette d'y mettre la dernière main. J'ai l'honneur d'être très-respectueusement,—Monsieur, Votre très-humble et très-obéissant serviteur.—LAVOISIER, De l'Académie des sciences.

Paris, le 19 Novembre, 1790.

M. Terray, Monsieur, m'a remis, en arrivant à Paris la lettre que vous m'avez fait l'honneur de m'écrire le 24 Octobre; il ne pouvait me faire un présent qui me fût plus agréable. J'ai cru que vous ne désapprouveriez pas que je la communiquasse à l'Académie des Sciences; elle n'a pas moins admiré l'élégance du style que la profondeur de philosophie et la candeur qui règne dans votre lettre, et elle a même désiré qu'elle fût déposée dans ses regis-

tres; mais je n'y ai consenti, qu'à condition qu'il m'en sera remis une copie certifiée du secrétaire. J'ai une autre grâce à vous demander, mais sur laquelle je dois attendre votre avis; c'est de vouloir bien me permettre d'en publier la traduction dans les Annales de Chimie. M. Gillan a été témoin, depuis son séjour à Paris, de quelques expériences que j'ai faites sur la respiration et il a bien voulu y concourir. Nous nous sommes assurés des faits suivants.

1. La quantité d'air vital ou gaz oxygène qu'un homme en repos et à jeun consomme, ou plutôt convertit en air fixe ou acide carbonique, pendant une heure est de 1200 pouces cubiques de France environ, quand il est placé dans une température de 26 degrés.

2. Cette quantité s'élève à 1400 pouces, dans les mêmes circonstances, si la personne est placée dans une température de 12 degrés seulement.

3. La quantité de gaz oxygène consommée, ou convertie en acide carbonique, augmente pendant le temps de la digestion et s'élève à 1800 ou 1900 pouces.

4. Par le mouvement et l'exercice on la porte jusqu'à 4000 pouces par heure et même davantage.

5. La chaleur animale est constamment la même, dans tous ces cas.

6. Les animaux peuvent vivre dans de l'air vital ou gaz oxygène, qui ne se renouvelle pas, aussi longtemps que l'on le juge à propos, pourvu qu'on ait soin d'absorber, par de l'alcali caustique en liqueur, le gaz acide carbonique, à mesure qu'il se forme; en sorte que ce gaz n'a pas besoin, comme on le croyait, pour être salubre et propre à la respiration d'être mélangé avec une certaine portion de gaz azote ou Mophete.

7. Les animaux ne paroissent pas souffrir dans un mélange de 15 parties de gaz azote et d'une partie de gaz oxygène, pourvu qu'on ait de même la précaution d'absorber le gaz acide carbonique, par le moyen de l'alcali caustique, à mesure qu'il est formé.

8. La consommation du gaz oxygène et sa conversion en acide carbonique est la même dans le gaz oxygène pur et dans le gaz oxygène mêlé de gaz azote, en sorte que la respiration n'est nullement accélérée en raison de la pureté de l'air.

9. Les animaux vivent assez longtemps dans un mélange de deux parties de gaz inflammable et d'une de gaz oxygène.

10. Le gaz azote ne sert absolument à rien dans l'acte de la respiration et il ressort du poulmon en même quantité et qualité qu'il y est entré.

11. Lorsque par l'exercice et le mouvement on augmente la consommation de gaz oxygène dans le poulmon, la circulation s'accélère; ce dont il est facile de s'assurer par le battement du poulx; et en général lorsque la personne respire sans se gêner, la quantité de gaz oxygène consommée est proportionnelle à l'augmentation du nombre des pulsations multiplié par le nombre des inspirations.

Il est bien juste, Monsieur, que vous soyez un des premiers informés des progrès qui se font dans une carrière que vous avez ouverte, et dans laquelle nous nous regardons tous comme vos disciples. Nous suivons les mêmes expériences, et j'aurai l'honneur de vous faire part de mes découvertes ultérieures. J'ai l'honneur d'être avec un respectueux attachement, Monsieur, votre très-humble et très-obéissant serviteur,—LAVOISIER.

ASSIMILATION OF KREATINE BY PLANTS.

By CHARLES A. CAMERON, M.D., &c.

WAGNER, in *Versuchs Stationer Organ*, xiii., 69 to 75, and 218 to 222, describes the results of his experiments with kreatine as a source of nitrogen for plants. Maize plants grew and developed seeds in a solution in which kreatine was the only nitrogenous substance present. The

kreatine was absorbed unchanged, and was detected in the plants. Wagner refers to the fact that Hampe had found that urea is absorbed unaltered by plants. The same observation was made by me in 1857, and was reported in the *Transactions of the British Association* for that year, in the *Chemist* for November, 1858, and in the *Repertoire de Chemie, Pur et Appliquée*, Paris, December, 1858. I find that plants can absorb unchanged, and apparently derive nitrogen from, potassic nitrite, potassic cyanurate, and potassic ferrocyanide.

NOTICES OF BOOKS.

Inorganic Chemistry for Elementary Classes. By W. A. SNAITH, M.A., Ph.D., F.C.S., F.E.J.S.

This little book contains in a concise form all that pupils require to know in order to pass the Examination of the Science and Art Department. So says the preface, and the description is strictly correct. Science teachers who wish to earn money in the May Examinations in Chemistry could not possibly pursue a more effectual course than to make their pupils get up the subject from this book. The first seven pages give definitions of Elements and Compounds; Atoms and Molecules; Absolute, Active, and Latent Atomicity; Simple and Compound Radicals; Acids, Bases, and Salts; Oxacids, Hydracids, and Sulphacids; Glyptic, Graphic, Symbolic, Empirical, Rational, and Constitutional Formulæ. Then follow a Glossary of Chemical Terms—the Laws of Boyle, Ampère, and Gay-Lussac, &c.; a Table of the Elements classified into Perissads and Artiads; a table, occupying thirteen pages, of constitutional formulæ; and an explanation of graphical formulæ.

These subjects occupy two-thirds of the book; the last third contains statements of chemical facts concerning hydrogen, chlorine, oxygen, boron, carbon, nitrogen, sulphur, and their compounds. Candidates who know this book off by heart will, we repeat, be almost sure of success at the Examination of the Science and Art Department. If, however, the object of the teacher be really to teach chemistry—and not merely to "pass" his pupils, the case is somewhat different, and Dr. Snaith's little book can hardly be recommended. Indeed, we can conceive no more effectual method of disgusting a pupil with the whole subject than to require him to commit to memory the definitions and formulæ which constitute the bulk of this book before entering on the study of the properties of the elements and their compounds.

It is, no doubt, important that the examiner for so influential an agency as the Science and Art Department should be one of the most eminent men in his profession, but it is clearly unfortunate for the interests of science when he is devoted to such a hobby as this system of graphical formulæ, and shows by his papers that a knowledge of the theories of the constitution of bodies is more highly regarded than a knowledge of the properties of those bodies. The existence of the book before us is a significant illustration of the working of the system of "payment on results" by which the Department seeks to assist science.

In 1870, £20,000 was paid by Government to science teachers. We venture to assert that if this sum were expended each year in founding a genuine school of science with efficient teachers, the benefit really rendered to science would be many times greater than that at present attained.

Still, for the object it proposes to secure, this little book is by no means badly compiled. It is cheap—is very well printed, and, in most cases, gives fairly good explanations.

Some of the definitions, however, are scarcely satisfactory, as the following quotations will show:—

Allotropic.—A body having different forms.

Deflagration.—The vivid combustion that is produced when the nitrates and some other salts are exposed to a red heat.

Precipitate.—The substance dissolved in a fluid which falls to the bottom on the addition of a reagent, and is left on the filter in the act of filtration.

Sublimation.—A process by which volatile bodies are condensed by cold into a solid form.

Carbonic Anhydride.—A colourless gas, with a slightly acid taste and smell.

On the Sanitary Improvement of Towns and the Utilisation of the Refuse. London: Waterlow and Sons, 1871.

THIS is a pamphlet illustrative of the Goux system of utilising and collecting the excreta of towns. The system, as applied to portions of the camp at Aldershot, has received very favourable reports; it has also been largely adopted at Halifax. The principle of the system consists in allowing the excreta to fall upon an absorbent material, which takes up the liquids and withdraws them from the action of the oxygen of the air. The absorbents employed are chaff, chopped or broken straw, damaged or refuse hay, coarse grasses, moor grass, dry street sweepings, dry horse-dung and litter, sweepings of markets, wool and hair, charcoal dust, dry fern, &c. Any or all of these are mixed in such proportion as may be most convenient, together with a small percentage of sulphate of iron or sulphate of lime. The receptacle may be a wooden tub, the sides and bottom being lined with the absorbent material. The system appears easily adaptable, the cost of conversion or fixing in the Borough of Halifax averaging from 7 to 35 shillings each house according to the style of fitting, &c. The system can also be employed in the case of receptacles of kitchen refuse. The agricultural value of the manure is said to be considerably above the average, while the dry nature of the contents of the tubs facilitates transport. The closets on this system are well adapted to factory purposes.

An Introduction to Practical Chemistry, including Analysis.

By JOHN E. BOWMAN, F.C.S., late Professor of Practical Chemistry in King's College, London. Edited by CHARLES L. BLOXAM, F.C.S., Professor of Chemistry in King's College, London. Sixth Edition. London, J. and A. Churchill, 1871.

THE author of this work selected for a prefatory note the celebrated quotation from Whewell's "Philosophy," "Facts are the materials of science, but all facts involve ideas. Since, in observing facts, we cannot exclude ideas, we must, for the purposes of science, take care that the ideas are clear and rigorously applied." This view has, indeed, been rigorously followed by both the author and the editor, and the result is a most comprehensive manual. This sixth edition presents many important additions. The entire course of qualitative analysis has been revised, and many of the examples in quantitative analysis are new, the weights employed being given in terms of the French as well as of the English standard. True to its title the work is essentially practical. It recommends itself to students by showing how chemistry may be thoroughly studied at a minimum of expense. The most practical chapter is, perhaps, that upon the methods of improvising reagents. Given the primary chemicals, as they are termed, or those indispensable to the analyst's cabinet, and consisting of sulphuric acid (vitriol), carbonate of soda (washing soda), chloride of sodium (common salt), nitrate of potash (saltpetre), sulphur (brimstone), ammonia (hartshorn), lime, bichlorate of soda (borax), ferrocyanide of potassium (prussiate of potash), carbonate or sulphate of baryta (heavy spar, barytes), sulphate of magnesia (Epsom salts),

litmus (Archil); the work explains how, with such common materials as may be everywhere procured, all the reagents absolutely necessary for qualitative analysis can be improvised. For instance, acetate of lead may be prepared by leaving scraps of lead or shot in an open bottle partly covered with vinegar until the latter is distinctly sweet. The preparation of hydrochloric and nitric acids is in a similar manner left to the student, who thus acquires a far more practical knowledge of his subject than can ensue from the employment of purchased reagents. Not a less important chapter, in its way, is that detailing the blowing of the several minor glass vessels used in analysis. The author and editor have, in short, done their best to make the student independent by placing before him an epitome of their extended experience couched in the simplest language. Besides the qualitative and quantitative estimation of the most commonly occurring substances, there are included tables of the solubility of salts; the percentage of anhydrous acid in dilute sulphuric acid as estimated by specific gravity; similar tables for nitric and hydrochloric acids; for anhydrous potash in solutions of potash, soda, ammonia; absolute alcohol in dilute alcohol; and the specific gravities of mixtures of ether and alcohol in different proportions. The work is concluded with a glossary of chemical terms, and an alphabetical table showing the action of reagents on oxides and acids. The manual cannot be too strongly recommended to the notice of the student.

CORRESPONDENCE.

RELATION OF HEAT TO ELECTRICITY.

To the Editor of the Chemical News.

SIR,—In the absence of any information as to the internal resistance and electromotive force of the cells employed by Mr. Highton, it is difficult to hazard an explanation of his results. It seems probable, however, that the internal resistance of the iron-carbon cell was the greatest, and also its electromotive force, the latter owing, perhaps, to the polarisation of the platinum. Under these circumstances the zinc-platinum pair would give the greater current with the small resistance of the galvanometer, while, against the large resistance of the platinum wire, the conditions would be reversed.

Mr. Highton must be aware that current-strength is dependent on resistance, yet he does not seem to have taken this at all into account. I venture to believe that if he will include the tangent galvanometer in the circuit, with such a length of platinum wire in each case as to reduce the current to the same amount, the temperatures will be sensibly equal. The length of wire heated is, of course, dependent not on the heating effect of a given current, but on the power of the cell to overcome resistance.

In conclusion I would suggest that it would give much more confidence in Mr. Highton's results, if before questioning laws which are the result of much patient and accurate investigation, he would make careful quantitative measurement of all the elements involved.—I am, &c.,

HENRY R. PROCTER.

North Shields,
November 28, 1871.

EQUIVALENTS VERSUS ATOMS.

To the Editor of the Chemical News.

SIR,—I notice in the last number of the *Journal of the Chemical Society* that a great liberty has been taken with

a paper published by M. Berthelot, the well-known Professor of Organic Chemistry in Paris, inasmuch as the whole of the equivalent formulæ in this paper have been changed into the atomic notation, *which he never uses*. Now, as Berthelot, Henri St. Claire Deville, Boussingault, Fremy, Regnault, Cahours, and a considerable number of eminent chemists not only in France, but also in Germany, Switzerland, America, and even in England, *never use the atomic notation*, but adhere to the simpler method of equivalent formulæ, perhaps you will allow me to protest against the extraordinary custom of changing the formula used by any author in making abstracts of his papers.

It will be urged, perhaps, that it is done for the sake of uniformity, but in the *Bulletin of the Chemical Society of Paris*—the model journal—such an extraordinary liberty is never taken, though a more enthusiastic atomic chemist than M. Wurtz it would be difficult to find. But as a man of talent and experience M. Wurtz is aware that our science is in a state of rapid transition, and, perhaps, he feels that it is more than probable the atomic notation now in fashion with so many of the younger and less illustrious of organic chemists (who are constantly writing, but rarely making discoveries) will ere long cease to exist; nay, that a return to the old equivalent dualistic notation of Berzelius by them would not be without its advantages. However that may be, let them look up to M. Berthelot as their great model—let them rest assured that he sees further into chemical futurity than any of them do—and, above all, let them study his writings *in the original* if the “abstractors” of the Chemical Society’s *Journal* are to mutilate and disfigure them as aforesaid.—I am, &c.,

Burlington House,
Dec. 4, 1871.

EQUIVALENT.

MISCELLANEOUS.

Smoke Drainage.—The Rev. B. W. Gibsons, M.A. B.Sc., has forwarded us a letter of his which appeared in the *Times* of Nov. 24. In it he asks “Why we should use chimney-stacks at all; one downward flue terminating in the water-drains would suffice to each house for the removal of its smoke.” In reply to the objection—“heated air will ascend and cannot be induced to descend without great external constraint”—he says that if the drains of any district or block of houses are connected with a ventilating furnace having a lofty ornamental shaft, there would be at once obtained the motive current of air, and a means of destroying the noxious gases of our underground system, while the central furnace would supply warm air or water, or even gas, to all the contiguous dwellings, and the heavy fuliginous matters would be condensed chiefly in the sewers; the result would be—

1. Absence of smoke in a city atmosphere.
2. Diminution of cost in construction of various chimney-stacks.
3. Absence of architectural disfigurements, such as zinc cowls and red cylindric pots.
4. Saving of fuel by total consumption of the smoke in the grate, the fire burning downwards instead of upwards.
5. Greater ease in cleansing the flue from soot, and in the removal of ashes.
6. Steadiness and irreversibility of air-draught, and power of thoroughly ventilating a room even when unfurnished with a fire. Mr. Gibsons’s idea is not a novel one; the same idea occurred many years ago to Mr Spence, of Manchester, but the difficulty of getting sufficient draught was so great that it could not be carried out. A tower of an impracticable diameter would have to be erected, and the leakages into the sewers would be so numerous that, at a distance of 100 yards from the tower, no appreciable effect would be produced.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the “Jahresberichte.”

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 16, 1871.

This number opens with the announcement of the death of Dr. Adolph Strecker, a well and deservedly known *savant* and scientific chemist, a member of this society, author of an excellent work on chemistry, and a constant contributor to the scientific periodicals of the German Empire. The deceased was Professor at Würzburg (Bavaria), and had just completed his fiftieth year.

This number contains the following original papers and memoirs:—

Formation of the Chrysanissic Acid and of an Acid Isomeric with it Belonging to the Meta Group.—H. Salkowsky.—While the formula of the chrysanissic acid was found by the author, in earlier researches on this subject to be—

the origin of this acid, by the nitration of nitro-anissic acid, remained unexplained. The continued investigation of this subject has led to the discovery that the formation of chrysanissic acid is due to the presence of dinitro-anissic acid present in the crude product of the nitration of the nitro-anissic acid, the dinitro-anissic acid having been separated from that crude material, by treating it first with a very dilute solution of carbonic acid, and next precipitation by means of carbonate of soda and purifying with alcohol. The dinitro-anissic acid exhibits a crystalline mass, of a somewhat yellowish colour, insoluble in water, fusing at about 172°, and composed of—

Ammonia converts this acid into chrysanissic acid, while alkalis convert dinitro-anissic acid into that kind of dinitro-oxybenzoic acid which is derived from chrysanissic acid. This substance is, therefore, to be considered as dinitro-para-amidobenzoic acid, and the oxy-acid derived from it as dinitro-para-oxybenzoic acid.

Contribution to our Knowledge of the Direct Formation of Aromatic Amido-Derivatives.—H. Salkowsky.—The contents of this paper partake of the nature of a preliminary notice, and bear upon the formation of some of the amido-derivatives of the aromatic series, viz. picramide, trinitro-aniline from trinitro-benzol, chloranilamide, and chloranilaminic acid from tetrachlorochinon. The author has extended the researches on this subject to those nitrated compounds of benzol which yet contain the remnants OCH_3 and OC_2H_5 of alcohol; thus picric acid ether, $\text{C}_6\text{H}_2(\text{NO}_2)_3\text{OC}_2\text{H}_5$, and trinitro-anisol—

form, when treated with ammonia, picramide.

Composition of Minerals Containing Tantalum and Niobium.—C. Rammelsberg.—This paper contains an epitome of the author’s extensive researches on this subject. We regret that, owing to the necessity of reproduction of a large number of complex formulæ, we cannot enter into details on the contents of this essay.

Behaviour of Monochloro-Acetic Acid with Methyl-Guanidin and other similar Compounds.—H. Huppert.—In the introduction to this essay, the author discusses, and illustrates with a series of complex formulæ, the constitution of kreatine, and its synthesis from sarkosin and cyanamide. When an aqueous solution of chloro-acetate of methyl-guanidine is heated during twelve hours to 120°, next boiled with hydrated oxide of lead, the liquid filtered, and the lead from the filtrate removed by sulphuretted hydrogen, the liquid again filtered, and next evaporated to the consistency of a syrup, a crystalline mass is obtained, $\text{C}_4\text{H}_7\text{N}_3\text{O}_5$, a body readily soluble in water, fusing without decomposition at a higher temperature, combining with acids, and the chlorhydrate forming, with platinum chloride, a double salt. This new body differs from kreatine by containing H_2O more. The constitutional formula of this substance, which is named glykyl-methyl-guanidine is—

By the action of chloro-acetic acid upon morphine, the author obtained a crystalline compound, readily soluble in water, which appears to belong to the same class of substances.

The concluding pages of this number are devoted to an exhaustive biography of the late Dr. George Cajetan Kaiser, an eminent German *sacant* widely known for his erudite and extensive knowledge of technology and pharmacy as well as chemistry and mineralogy. The deceased was an excellent lecturer, and occupied for a series of years the Chair of Chemistry at the Lyceum at Landshut, Bavaria.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale,
August, 1871.

This number opens with a very exhaustive memoir:—

Report on Lead Pipes Coated Inside with a Thin but Continuous Layer of Black-Tin.—M. Tresca.—Although this subject does not belong to chemistry, we call attention to this memoir, which enters exhaustively into the particulars of an industry which is carried on in Paris by M. Hamon, who has succeeded in making the tubes alluded to by a greatly improved process, so that the thickness of the tin is reduced to $\frac{1}{2}$ millim., while yet all the advantages of black-tin pipes are obtained. This memoir is illustrated by engravings.

This number does not contain any original papers on chemistry, but we notice the following essay:—

Cultivation of the Chinese Nettle (*Urtica Nivea*), Mode of Preparation of the Bark of this Plant, and Application of the Textile Fibres it Yields.—M. Ramon de la Sagra.

Les Mondes, November 30, 1871.

Hydrometre Clauzottes.—A brief description is given of a water-meter invented by the author just named, which instrument is stated to be the most perfect and accurate of its kind hitherto brought out, yet, at the same time, simple in action, and capable of working under very low as well as very high pressure without failing to give correct indications.

Description of a Newly-Invented Colorimeter.—M. Salleron.—Without the reproduction of the woodcut annexed to this paper it is not possible to enter into details on this instrument, but the results of the experiments made by the excellent Editor of this paper prove it to be very superior, as may be inferred from the following quotations (the quantities of the undermentioned substances refer to weight [grms.] in 1 litre of water, while the next following figure designates the quantity of the substance first mentioned and detected by the instrument):—Caramel, 2.5, 0.0012; fuchsine, 0.01, 0.00007; aniline blue, 0.01, 0.00005; cochineal, 0.1, 0.0002; Prussian blue, 0.05, 0.0004; sap green, 0.2, 0.0006; gamboge, 0.2, 0.0006; logwood extract, 0.2, 0.0002; indigo, 0.02, 0.0002; tincture of litmus, 0.02, 0.0003.

Journal de Pharmacie et de Chimie, October, 1871.

This number contains the following original papers and memoirs:—

On Bromide of Potassium.—Dr. Falières.—A great portion of this memoir relates strictly to therapeutics, but, as regards the testing of the purity of bromide of potassium and its preparation more especially for medicinal purposes, the following suggestions are made:—1 gm. of bromide of potassium, previously pulverised, and put into a glass-stoppered bottle, is dissolved in from 30 to 40 grms. of distilled water. To this solution is added a solution of nitrate of silver, containing 1.427 grms. of that salt. When the precipitate has settled, there is added to the liquid, by means of a burette, a drop of a decinormal solution of nitrate of silver, which, if the bromide is pure, will not produce any further precipitate—the fact being that 1 gm. of the bromide requires precisely 1.427 grms. of nitrate of silver for precipitation, while 1 gm. of chloride of potassium requires 2.279 grms. of the argentic nitrate. It is clear, however, that the bromide will have to be tested for the absence of iodide, carbonate, and sulphate of potassium, and of nitrate of soda. As regards the preparation of bromide of potassium, the author proposes the following process:—100 grms. of bicarbonate of potassa are dissolved in 500 grms. of water; to this solution, 80 grms. of pure bromine are added, and, as soon as the effervescence ceases, there is also added a mixture of 90 parts of pure distilled water and 30 parts of liquid ammonia (sp. gr. = 0.875). The liquid is next evaporated to dryness, care being taken to apply a gentle heat as long as any vapours of carbonate of ammonia are given off. The residual saline mass is next ignited, so as to convert the bromate of potassa into bromide of potassium; the salt thus obtained is, after cooling, re-dissolved in pure distilled water, an aqueous solution of bromine added to this solution, which is next evaporated for crystallisation. By the addition of the ammonia, bromide of ammonium is first formed, and this salt, acting upon the undecomposed carbonate of potassa, converts it into bromide, while carbonate of ammonia is volatilised.

Preparation of Neutral Sulphate of Eserine.—A. Petit.—The hydro-alcoholic extract of Calabar beans is dissolved in water *q. s.* (1 part of the extract to 4 of water). This solution is filtered, and to it is, for every 20 grms. of extract, added 1 gm. of bicarbonate of potassa; there is next added an excess of ether, with which the liquor is thoroughly mixed, by shaking in a glass-stoppered bottle. The ether is gently decanted from the aqueous fluid, an operation best performed by a funnel, to the neck of which a tap is fitted. To the ethereal fluid, which contains eserine, is first added some distilled water, and next, drop by drop, dilute sulphuric acid (strength, 40 grms. of monohydrated sulphuric acid to 1 litre of distilled water), so that

one drop = 0.05 grm. of acid, corresponds with the necessary quantity of eserine to form 0.01 grm. of neutral sulphate of eserine. The aqueous acid solution is next evaporated to dryness upon a water-bath, leaving the crystalline compound of sulphate of eserine.

Vienna Yeast.—Dr. Vigls.—This yeast is prepared in the following manner:—Previously malted barley, maize, and rye are ground up and mixed, next put into water at a temperature of from 65° to 75°; after a few hours, the saccharine liquid is decanted from the dregs, and the clear liquid brought into a state of fermentation, by the aid of some yeast. The fermentation becomes very strong, and, by the force of the carbonic acid which is evolved, the yeast globules (the size of which averages from 10 to 12 millims.) are carried to the surface of the liquid, and, forming a thick scum, that substance is removed by a skimmer, placed on cloth filters, drained, washed with a little distilled water, and next pressed into any desired shape by means of hydraulic pressure, and covered with a strong and stout tightly-woven canvas. This kind of yeast keeps for from eight to fourteen days according to the season, and is, both for bakers and brewers, very superior to that ordinarily used; the extra good qualities of Vienna beer and bread are partly due to the use made of this yeast in preparing these articles.

Annalen der Physik und Chemie, von Dr. J. C. Poggenдорff, No. 9
1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

On Electrolysis and Conductibility through Fluids.—G. Quincke.—An algebraico-physical essay.

On Apparatus and Methods of Observing for Crystallographic-Optical Researches.—P. Groth.—This memoir, illustrated by a series of engravings, is divided into the following sections:—Polarisation instrument; the stauroscope; apparatus for determining the axial angles; goniometer.

Intrinsic Nature of Gases.—G. Hansemann.—An algebraico-physical essay; an observation also bearing upon the following paper:—

Influence of Astronomic Motion on Optical Phenomena.—E. Ketteler.

On Anomalous Dispersion, viz., of Rays of Light.—A. Kundt.—The third portion of an optical essay, illustrated by several engravings.

Method of Filling Barometer Tubes without the Necessity of Boiling the Mercury and without the Danger of Breaking the Tube.—H. Wild.—The author describes at length, and illustrates by engravings, an ingenious method of filling barometer tubes; while the second part of the paper refers to the purifying of mercury. Take 1000 grms. of that metal, pour it into a strong flask capable of holding 2000 grms. of water. Take, next, 30 grms. of a solution of chloride of iron (made up of 1 part of the dry salt and 3 parts of water), add this to the mercury, and, after having closed the flask with a cork, shake it vigorously until the metal is so finely divided that with the naked eye no more globules can be seen. Water is next poured into the flask, and the contents, having been well agitated, are left for a moment to settle, and the impure solution poured off; this operation is repeated twice, after which the greyish mass of very finely divided metal is poured into a porcelain basin, which, having been placed on a water-bath, is made dry, and next brought to its normal state of aggregation by rubbing in a glazed porcelain mortar. The metal is next filtered through good tough writing-paper wherein a perforation has been made with a needle.

Contribution to Micro-Mineralogy.—Dr. A. von Lasaulx.—A paper illustrated by a series of engravings exhibiting magnified figures of crystals.

Sitzungsberichte der Mathematisch-Physikalischen Classe der Königlich Bayerischen Akademie der Wissenschaften zu München, vol. II., 1871.

The original papers and essays relating to chemistry published in this volume are the following:—

Fat Contained in Beer-Yeast.—Dr. Vogel.—After referring first to the fact that all cereals contain a larger or smaller quantity of fatty matter, which is an essential constituent of the grain, the author describes at length his experiments made for the purpose of extracting, by means of ether, the fat contained in beer-yeast, an oil boiling at about 200°; sp. gr. = 0.901; decomposed when heated above 300°, and yielding acrolein. The quantity of this oil found in 1 litre of the yeast amounts to from 0.2 to 0.3 grms. It appears that that this oil is in most respects akin to the fatty matter found in barley. The greater part of the contents of this paper bears particularly on *zymotechny*.

Fossil Resin which perhaps Belongs to the Flora of the Amber.—If. Spigatis.—The author obtained a specimen of a kind of soft substance, occasionally found along with amber in that portion of the Baltic (situated near the coast of East Prussia) where dredging for amber is regularly carried on. This soft material is vulgarly known as a unripe amber, a soft semi-elastic substance, which hardens gradually by exposure to air; sp. gr. = 0.934; insoluble in caustic alkalies, oil of turpentine, alcohol, and also insoluble in chloroform, sulphide of carbon, and petroleum, which have the effect, however, of softening this substance and making it swell; benzol only dissolves out a small portion of an essential oil, while ether, in addition to the latter, also dissolves some of the resin, which was found on analysis to consist, in

100 parts, of:—Carbon, 86.02; hydrogen, 10.93; oxygen, 3.05; formula, $C_{40}H_{12}O$. The author observes that the composition of this resin is very different from that of amber (which contains, after deducting ash, in 100 parts, according to Schröter:—Carbon, 78.60; hydrogen, 10.19; the rest being O), while the composition of this resin is more like that of the fossil resin of Settling-Stones, which, according to the late Professor Johnston, contains, in 100 parts:—Carbon, 85.25; hydrogen, 11.03.

On Rammelsbergite.—F. Sandberger.—This rather rare mineral, also known as Weissnickelkies, was found to have a sp. gr. = 7.19, and consists, in 100 parts, of:—Arsenic, 63.30; nickel, 26.65; iron, 2.06; bismuth, 2.662; with traces of copper, cobalt, and sulphur.

Influence of the Germination Process on the Fat Contained in the Seeds.—Dr. Vogel.—From the contents of this essay it appears that, by the process of germination, the quantity of fat contained in seeds decreases in the ratio of from 0.094 to 0.320 per cent; average, 0.156 per cent.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
November 23, 1871.

This number contains the following original matter:—

Notice on Glue, Cements, Lutes, &c., in Reference to their Mode of Application.—Dr. Sibon.—The contents of this paper are chiefly of interest to those whose daily vocation is the use of cements for the purpose either of mending glass, china, small articles made of wood, horn, &c., or the use of the materials alluded to in the construction, for instance, of physical instruments wherein it is required to unite glass and metals together.

Description of a New Telegraphic Instrument.—M. Chamberlain.

Magneto-Electric Explosion Apparatus.—J. Breguet.—Illustrated by a woodcut. A very ingeniously-devised instrument constructed for the explosion of gunpowder, dynamite, nitro-glycerine, and gun-cotton, in mines, quarries, and also in warlike operations.

Resistance Offered by Air Against the Motion of an Air-Balloon.—H. Mangan and D. Clay.—A mechanico-physical paper, recording the results of some experiments made at the Orléans railway-station with two air-balloons, respectively of 6 and of 10.75 metres diameter.

NOTES AND QUERIES.

Naphthalic Acid.—Will some reader please tell me the readiest way to make naphthalic acid?—NAPHTHALINE.

Comparative Tables of Hydrometers.—Can any of your readers inform me where I can procure a good book or journal giving the comparative tables of Twaddell's hydrometer with that of Baumé.—L. C.

Spence's Process of Treating Mineral Phosphates in the Manufacture of Artificial Manure.—I shall be glad if some of your readers will give more details of this process than are contained in your brief report of Dr. Wallace's Address at the Glasgow Philosophical Society, on Monday, Nov. 6.—W. L.

Apparatus for the Liquefaction of Gases.—I should feel obliged if any of your correspondents would give, or refer me to, a good detailed description of the valve to the receiver in Natter's apparatus for the liquefaction of gases. There is a description in Ganot's "Physics," p. 260, but it is too general for my purpose.—S. T.

Gas-Proof Fabric.—Can any of your numerous readers inform me, through the medium of your "Notes and Queries," how I can make linen or cotton fabric gas-proof? I have made a large gas-bag of cotton cloth, and want an oil-varnish of some sort that will render it as impervious to gas as oiled silk is. India-rubber varnish will not do, as it is liable to become soft and adhesive after a time if moisture come in contact with it.—L. R. C. P. Edin.

Adulterations in Food and Drink.—Can any of your correspondents tell me if there is any book or books which give simple but trustworthy directions for detecting adulteration in food and drink? The processes given by Hassall and Normandy are long and complicated, and often imperfect. The food analysts appointed by various towns and counties must have some such processes, as they are required by the Act of Parliament to complete their analyses in a very short time.—AN AMATEUR CHEMIST.

Test for Starch.—I do not know if it has escaped the notice of chemists that iodine is not a test for starch in solutions of sugar, brewer's wort, albumen, &c. It is customary with some brewers to test their wort for starch, which, though very likely to be present, they never find. I have added starch to wort before testing with iodine, and you may guess my surprise on applying the test at not having the usual reaction. The starch was not at once converted, for on the application of a stiff dose of SO_2 I had the starch reaction. My solutions were cold and acid.—ALFRED TERRY.

Coagulation of Clay.—(Reply to X. Y. Z.)—Chloride of iron and carbonate of soda, in the proportion of 32 kilos. of the former salt and 84.5 of the latter to a quantity of water equal to 1000 cubic metres, has been found a most valuable and quite innocuous means of purifying water, even such as is otherwise quite unfit for drinking purposes and could not be rendered so by alum. The salts alluded to are best

previously dissolved in some pure water, and the solutions, that of iron first, poured into the tank containing the water intended to be operated upon. The soda solution is not added until after a few moments, the water being first vigorously stirred. The soda solution having been added, the fluid is stirred again, and then left quiet for the purpose of allowing the very bulky and flocculent sediment to deposit; this takes considerable time—from twenty-four to thirty-six hours. The *strychnos potatorum* is used in India for purifying clayey water.

The Milanese Sewerage System.—This is recommended by Mr. Child, of Oxford, as being suitable for small towns and country villages. Its essential feature is the drainage of the houses into water-tight cesspools, which are emptied frequently, efficiently, and quite inoffensively by means of a barrel-cart, previously exhausted of air, and a hose. The barrel-cart then conveys the sewage to a depot at a convenient distance, where all that is saleable is sold to farmers, and the rest is manufactured into a kind of dry artificial guano. Many of our little towns and villages lie on dead flats or at the bottom of deep valleys, where ordinary sewerage works could not be established without an expensive provision for raising the sewage in order to render it available for irrigation. In such places the Milanese system might be carried out with ease and at comparatively small outlay. A certain number of cesspools would be rendered water-tight—a process not very expensive. One cesspool would serve for several cottages, and frequent emptying would be better than large size. Two Milanese barrel-carts must be procured, and these, with a small steam-engine at the depot to work the air-pump, would, together with about three men and two horses, form the whole of the apparatus required for testing the system upon a small but sufficient scale. On the day on which Mr. Child visited the depot near Milan, farmers' carts were waiting there literally in scores to obtain their supply of it, and he feels sure that if landed proprietors or farmers were to give the system a trial in this country they would find it well worth adoption.—*The Garden.*

MEETINGS FOR THE WEEK.

MONDAY, Dec. 11th.—London Institution, 4. Prof. Huxley, LL.D.
F.R.S., on "Elementary Physiology."

Medical, 8.
Royal Geographical, 8.30.

TUESDAY, 12th.—Civil Engineers, 8.
Photographic, 8.

WEDNESDAY, 13th.—Society of Arts, 8.

THURSDAY, 14th.—Royal, 8.30.
Royal Society Club, 6.

TO CORRESPONDENTS.

* * Vol. XXIII. of THE CHEMICAL NEWS, containing a copious index, is now ready, price 11s. 4d., by post, 12s., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 2s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxiv. commenced on July 7th, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each, post free, may also be obtained at the Office.

ERRATUM.—Vol. xxiv., p. 156, line 32 from top, for "2 atoms of nitrogen" read "4 atoms of nitrogen."

G. H. B.—Watts's "Dictionary of Chemistry."
A. T. Jones, Bilbao.—A work containing the information you require is in the press; it will be duly announced in our columns.

BOOKS RECEIVED.

Elementary Treatise on Physics, Experimental and Applied, for the Use of Colleges and Schools. Translated and Edited from Ganot's Elements de Physique. By E. Atkinson, Ph.D., F.C.S. London: Longmans, Green, and Co.
New Remedies; a Quarterly Retrospect of Therapeutics, Pharmacy, and Allied Subjects. By Horatia C. W. Wood, jun., M.D. New York: William Wood and Co.
The Journal of the Iron and Steel Institute, vol. ii. London: E. and F. N. Spon, Charing-Cross.
Tobacco; an Essay. By Henry Gibbons, M.D. London: James Burns.
Asiatic Cholera in Bristol in 1866. By William Budd, M.D., F.R.S. Bristol: T. Kerslake and Co.

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

TEXT-BOOKS OF SCIENCE.

On Tuesday, December 19th, in small 8vo., price 3s. 6d.,

The Theory of Heat. B. J. Clerk Maxwell, M.A., F.R.S.S., L. & E., Professor of Experimental Physics in the University of Cambridge.

Being the Sixth of the New Series of Elementary Works on Mechanical and Physical Science in course of publication, edited by Professor T. M. Goodeve, M.A.

Text-Books previously published, price 3s. 6d. each:—

1. GOODEVE'S MECHANISM.
2. BLOXAM'S METALS.
3. MILLER'S INORGANIC CHEMISTRY.
4. GRIFFIN'S ALGEBRA AND TRIGONOMETRY.
5. WATSON'S PLANE AND SOLID GEOMETRY.

London: Longmans, Green, and Co., Paternoster Row.

Now ready, Vol. I., New Series, cloth 8vo., price 2s., illustrated with Chrom-lithograph, 4 Page Plates, and 81 Woodcuts,

The Quarterly Journal of Science, and Annals of Mining, Metallurgy, Engineering, Industrial Arts, Manufactures, and Technology. Edited by WILLIAM CROOKES, F.R.S., &c.

London: Offices of the Quarterly Journal of Science, 3, Horse-Shoe Court, Ludgate Hill, E.C.

Royal 8vo., with 7 Lithographs and 50 Woodcuts, price 6s. cloth,

Microscopical Manipulation; being the subject-matter of a Course of Lectures delivered before the Quekett Microscopical Club, January—April, 1869. By W. T. SUFFOLK, F.R.M.S.

London: Henry Gillman, Boy Court, Ludgate Hill.

Just published, demy 8vo., with 42 woodcuts, price 1s.,

The Antiseptic System: A Treatise on Carbolic Acid and its Compounds, with an Inquiry into the Germ-Theories of Putrefaction, Fermentation, and Infection, the Theory and Practice of Disinfection, and the Employment of Antiseptics in Practical Medicine and Surgery. By A. E. SANSON, M.D., London, M.R.C.P.

London: HENRY GILLMAN, Boy Court, Ludgate Hill, E.C.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c.; of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily. Especial facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Silicates of Soda and Potash in the state of

Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C. who hold stock ready for delivery.

Royal Polytechnic.—Professor Pepper's New

Lecture, "ALL ABOUT GUN-COTTON," Dynamite, and Lithofructure; with brilliant and noiseless Experiments, and Graphic Illustrations of the CATASTROPHES at STOWMARKET, by Vick and Deazley.—Mr. George Grossmith, jun.'s New Sketch, THE SILVER WEDDING! with humorous and musical illustrations.

A perfectly new and unique Illusion called the ARABIAN MYSTERY.—Novel and marvellous effects of the ELECTRIC LIGHT UNDER WATER, by Messrs. Heinke and Davis.—Occasionally, PAKIS: as it Was and Is! by J. L. King, Esq., with Songs by Miss Alice Barth.—Open daily from 12 to 5, and 7 to 10.—Admission One Shilling.

ANALYTICAL LABORATORY AND SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied and the erection of Plant and Buildings is superintended when required.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1871—1872 will commence on the 2nd of October, when the Laboratories will re-open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, commencing October 2nd, at 8 p.m.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, commencing October 3rd, at 8 p.m.

The BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, commencing October 4th, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

AMSTERDAM EXHIBITION, 1869.

THE GRAND DIPLOMA OF HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2½d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar Sold by all Italian Warehousemen, Grocers, Chemists, and Ships Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, MARK LANE, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British French, Prussian, Russian, and other Governments.

Now ready, price 6d.,

Notes of Professor Odling's Juvenile Lectures on BURNING AND UNBURNING, delivered at the Royal Institution of Great Britain, Christmas, 1870-71.

London: Henry Gillman, Boy Court, Ludgate Hill, E.C.

THE CHEMICAL NEWS.

VOL. XXIV. No. 629.

ON THE CHEMICAL CONSTITUTION OF GLYCOLIC ALCOHOL AND ITS HETEROLOGUES, AS VIEWED IN THE NEW LIGHT OF THE "TYPO- NUCLEUS" THEORY.*

By OTTO RICHTER, Ph.D.

THE common saying, that "a tree is known by its fruits," applies with equal force to scientific pursuits, no matter whether these pursuits are carried on in the practical or in the theoretical department of human knowledge. The art and science of chemistry, from being a plain and simple record of systematically arranged facts, is now fast approaching that period of its development when, as a rational science, it will gain for itself a position fully as noble and imposing as that of astronomy, mechanics, optics, and other branches of applied mathematics. In pondering the various questions and problems which require to be solved before we can hope to attain this most desirable object, I was not slow in discovering that the garden of science enclosed within its precincts one of those rare and precious trees which, under judicious culture, might be made to furnish a plentiful crop of novel and original conceptions. It is now more than twenty years since I bethought myself of investigating the singular configuration and structure of that wonderful tree, as well as the internal organisation of its multifarious and matchless productions. Considering that it is imperative upon me to approach my subject in a spirit of the utmost fairness and candour, I feel it my duty to inform you that at no great distance from my own favourite tree of chemical knowledge there stands another and much older tree of chemical knowledge, which has for a considerable period enjoyed the privilege, or I should rather call it the monopoly, of supplying the chemical market with its bright and showy, but, upon the whole, spurious and unpalatable, productions.

The two trees of chemical knowledge above alluded to are in reality two different chemical theories, which, with many connecting links and points of resemblance between them, are nevertheless in their leading doctrines and principles vitally opposed to one another. The younger of these theories, which may appropriately be designated the "typo-nucleus" theory, is the offspring of my private meditations. Its general tenets and principles were first promulgated by me at the meeting of the British Association in Norwich in the year 1868, and a small pamphlet, entitled "General Outline of an Original System of Chemical Philosophy, comprising a determination of the Volume-Equivalents, as also a New Theory of the Specific Volumes of Liquid and Solid Substances," soon afterwards appeared in print, and was made known by means of advertisements. The older of these two theories, which may appropriately be designated the "typo-radical" theory, is, I scarcely need to tell you, the dominant and all but universally adopted system of our modern chemical schools and laboratories.

It is with the sincere and anxious desire of furthering the cause of scientific progress, which the founders of this world-famed Institution have chosen for their motto, that I have sought and obtained the kind permission of your Committee to lay before you a variety of experimental evidence in support of the validity of my assertions, which, if it does not convince you on the spot, will

at least, I flatter myself, set you to ponder and ruminate. The subject of my present discourse, by the aid of which I hope to illustrate a few of the many salient points which distinguish the "typo-nucleus" theory from its full-grown and powerful rival, bears for its title "The Chemical Constitution of Glycolic Alcohol and its Heterologues, as viewed in the new light of the 'Typo-nucleus' theory." But in order to enable you more fully to comprehend the scientific bearing and significance of these novel conceptions and doctrines, it is requisite that I should first of all explain to you the precise meaning of the compound terms "typo-nucleus" and "typo-radical." As regards the first of these components you may perhaps imagine that the word "typo" expresses one and the same idea in both theories. Let me at once disabuse you of this mistake. In my chemical system the seven principal types enumerated therein represent as many distinct and separate forms of molecular arrangement, and it is of importance to add that each one of these types embraces and characterises one single order of chemical compounds, and this order exclusively. In the "typo-radical" system, on the other hand, the word "typo" bears an essential different meaning, for it implies that, in accordance with the general law of substitution, chemical compounds may be systematically distributed over a few simple patterns, models, or types. The so-called rational formulæ employed for these types are meant to convey to the mind a more or less clear and definite idea of the relative position of the component elements, and likewise of their leading chemical properties and functions. The substances, whose chemical formulæ have been employed, or, I should rather say, "perverted" for this purpose are hydrogen, water, ammonia, chloride of ammonium, carbon, and marsh-gas. As regards the second of these compounds, namely, the expressions "nucleus" and "radical," a few remarks will suffice for determining the precise meaning of these critical and portentous epithets. Observe, then, first of all, that the two types of the simple hydrocarbon molecules and of the simple normal acid molecules are regarded in my system as the first self-supporting productions of the chemical forces, and that the various species of elementary molecules are all supposed to belong to the class of non-enveloped acid nuclei, and it is under this latter form that they occupy the first place in the series of normal acid molecules, and that like the rest of these members, they are believed to possess the power of uniting with the bases. The nuclei of the normal acids are further supposed to occur not singly, but always in pairs, in other words, as twin nuclei, and it is one of the distinguishing characteristics of their component nuclei that they cannot be represented by more than one bivalent molecule. You will, moreover, bear in mind that the other members of the acid series are produced from these twin nuclei by the successive introduction of one or two chemically similar elementary molecules into that particular region of the atomic edifice to which, from its contiguity to the nucleus compartment the term "envelope" has perhaps not unfitly been applied. The expression "radical" is commonly understood to refer to that section of a given atomic system which in the various chemical processes is observed to remain either totally unaltered, or to become modified in such a manner that, for every component molecule of one kind which is taken away, an equivalent molecule of another kind is supposed to step into its place so as to fill up the vacancy. Unfortunately this definition of the word "radical" holds good under the above restrictions only, and necessitates the exchange of one radical for another as often as the result of the experiment testifies to the fact that the loss of constituents in the radical has not been compensated by the accession of new elements. It is, therefore, not to be wondered at if this tendency to fluctuation in what ought to be the most stable and enduring portion of the atomic edifice continues to prove a source of serious trouble and embarrassment to the devisers and advocates of the typo-radical theory.

* Abstract of a Paper read before the British Association, Edinburgh Meeting, 1871.

In the language of one set of interpreters the atoms are said to be furnished with a variable number of movable poles or points of attraction, which they are able to turn in every direction, nay, if needful, even the one against the other; while in the language of a different set of interpreters, mere units of affinity are talked of and employed in their calculations. It is further alleged that the saturating capacity of the elementary molecules is exactly commensurate to the number of poles or units of affinity thus stored up within them. I, for my part, must confess that I cannot reconcile myself to either of these modes of interpretation, and more especially not to that grotesque and ludicrous exhibition of capers and summersaults which these *soi-disant* poles are made to perform within the walls of their globular dwelling. Let us now suppose that some of my hearers, impressed with the awkwardness of the situation, put this question to me: What would you advise us to do in order to extricate theoretical chemistry from its present unbecoming and ungraceful attitude? To this question I can return a ready and straightforward answer, and I will give it in the language of a musician who knows that in the strict style of contrapuntal writing, every discord ought to be duly prepared and resolved, and every licence avoided in order to produce in all the parts an agreeable and harmonious effusion of musical sounds. I boldly declare and maintain before this meeting that when this very ingenious and plausible, but philosophically untenable, polar hypothesis was, as it were, by way of licence, and without due preparation, brought to bear upon Gay-Lussac's famous law, that æiform elementary substances are capable of combining, in certain simple ratios of their specific volumes, a grave and fatal error was committed by our chemical guides and advisers. I must, therefore, strenuously protest against any further attempts of screening and propagating this error, which has been productive of incalculable mischief, inasmuch as it has laid the foundation for that narrow, hasty, and superficial style of arguing which our modern theorists, in their eagerness to establish rational formulæ, have thought proper to cultivate—a style which, in its wild and precipitous efforts to tear asunder in these formulæ, and to dislocate what, by Nature herself, is and ought to remain united, finds no parallel in the whole wide domain of natural philosophy. What, then, I ask in sober earnest, are the boasted advantages, which have accrued to theoretical chemistry from this incessant hunting and racing after multivalences and atomicities? I, for my part, can see none, and I must, therefore, denounce the whole movement, which is now in full swing, and which appears to be headed and fomented by a few highly-gifted, but rather overweening intellects, as being in reality a movement in a circle which, if persisted in, will simply land you at the same point from which you were starting some years ago, on what I cannot help stigmatising as a "wild goose chase," after the self-begotten phantoms of your own over-heated imagination. Thus, then, it has come to pass that the main problem of modern chemistry, the satisfactory solution of which will not fail to inaugurate a new era of scientific progress, has been utterly ignored and lost sight of. This problem may be stated as follows:—What is the truest, safest, and most trustworthy test and criterion for discriminating between the essential and the non-essential constituents of complex molecules, as well as for distinguishing between the various modes and forms of chemical union, whereby the essential constituents are cemented to each other and typically grouped together in conformity with the general law of chemical rank-order, representing, so to speak, the very bone and marrow of the molecular organism, while the non-essential constituents, from their greater mobility and readiness to dissociate themselves from that organism, are evidently connected with the former by much looser and more fragile ties of chemical affinity? And here I take the liberty of reading my translation from the German, of what may be considered a sort of public confession of the chemical

creed and convictions entertained by one of our most eminent continental chemists and philosophers. Professor Kolbe, of Leipzig, says in one of his numerous essays—I allude to the paper where he dilates on the derivatives of cyanamide:—"I have gained my point," says the learned Professor, "if I can succeed in convincing the reader how far those chemists have gone astray from the path of truth who flatter themselves that they have actually solved the problem of the chemical constitution of substances after they have managed to link together in due form and order all the elementary constituents of a given compound, but who fail to perceive that every group or constellation of atoms requires a ruling head or principal, around which the other members are destined to occupy a more or less subordinate position. The cause of this oversight is the erroneous impression, or, I should rather call it, the fashionable delusion that chemical combinations are comparable to sets of chains, open or closed, as the case may be, and whose component links are all equal in point of rank and superiority. I, for my part, would rather prefer likening these combinations to a regularly organised community, say, for instance, to a regiment of soldiers, which is composed of a colonel, subalterns, and commoners. In such a regiment the common soldiers are lower in rank than the lieutenants and captains, while the colonel is the highest in command, and every one must obey his orders." These, gentlemen, are the clearly expressed views and sentiments of one of our most intelligent and distinguished chemists, and I myself for one am ready to acknowledge their general veracity and correctness. But I must go one step farther by saying that although there is a strong resemblance between my acid twin nucleus with its subordinate adjuncts, and the commander of a regiment with its staff of adjutant officers, there is this vast and vital difference between us, that I have shaken myself entirely free from the shackles and trammels of the dominant school philosophy, while our esteemed colleague, who in his own person happens to be a mighty leader and spokesman on the typo-radical side, must be supposed to be still deeply enamoured of his long-courted and idolised mistress. After these rather lengthy but unavoidable preliminaries, I shall now do myself the honour of discussing before you the main subject of this paper, which bears for its title, "The Chemical Constitution of Glycolic Alcohol and its Heterologues, as viewed in the new light of the typo-nucleus theory."

(To be continued.)

ON THE
IRIDIUM COMPOUNDS ANALOGOUS
TO THE
ETHYLEN AND PROTOCHLORIDE OF
PLATINUM SALTS.*

By Professor SAMUEL P. SADTLER, Ph.D.,
Pennsylvania College, Gettysburg, Pa.

AMONG the compounds which we are accustomed to call *organo-metallic*, those of PtCl_4 and PtCl_2 play, perhaps, the most important part. We can separate them, however, into the two great classes—those where the PtCl_4 and PtCl_2 enter by substitution into compound ammonia atoms, and thus form bases more or less complex, but having still a certain connection; and those where the PtCl_4 and PtCl_2 take up organic radicals of different degrees of valence to form saturated compounds.

The range of this last class, as can be seen, is very wide; one of the most prominent of these compounds, however, and one which exercised for some time a very

* Extract from an Inaugural Dissertation at the Univ. of Göttingen, April, 1871.

considerable influence upon the theoretical views held at that time, is the compound of PtCl_2 , known as Zeise's salt, and discovered and investigated by him in 1830.

It is not necessary to recount here the controversy which took place between Zeise and Liebig on the subject. Suffice it to say that, by subsequent investigations of Griess and Martius and of Birnbaum, its formula is definitely settled as $\text{PtCl}_4 \cdot \text{C}_2\text{H}_4 + \text{KCl}$.

The investigation I now undertook was to see if a similar base of iridium could be prepared. Various considerations, stated at length in my original paper, led me to believe that iridium might not combine exactly as platinum did in the formation of these salts.

After obtaining the double chloride of iridium and ammonium in the usual way, by decomposing the osm-iridium, I made some tests as to the manner of formation of the salt. An attempt to form it by taking the double chloride of iridium and ammonium in solution, and, passing a stream of chlorine through to break up the chloride of ammonium, to then conduct ethylen gas into it, was unsuccessful. The method which succeeded most perfectly was to act upon iridium chloride. This was obtained by igniting the double chloride of iridium and ammonium, thus obtaining iridium oxide and metallic iridium, which was then heated with aqua regia in sealed tubes of Bohemian glass to 180° or 200°C . This solution of IrCl_4 I then treated with absolute alcohol. On adding KCl, and allowing it to crystallise out, I got the greenish-brown crystals of the iridium-ethylen base. On subjecting them to an organic combustion, I obtained as products carbonic acid and water. They burned with a luminous flame, and answered, in short, all the tests applied to Zeise's platinum salt.

Another experiment, to see if ethylen gas would act directly upon the IrCl_4 , reducing it and uniting at the same time, was unsuccessful.

It will thus be seen, that the only method of preparing the iridium-base is by the reducing action of alcohol on iridium chloride, according to the reaction:—

the products of which are iridium-ethylen-protoclchloride, hydrochloric acid, aldehyde, and water.

The purifying of the necessary iridium was found to be a very long and tedious operation, the last traces of platinum sticking very pertinaciously to the iridium salt. The processes in use also leave much to be desired in the way of completeness and expedition.

The method selected for separation was the method of Birnbaum, grounded upon the distinct and separate crystallisation of the double cyanides of iridium and barium, and platinum and barium. To convert the double chlorides of iridium and ammonium, and platinum and ammonium, into the double cyanides of iridium and potassium, and platinum and potassium, after trying Wöhler's and Muckle's method and obtaining unsatisfactory results, I had recourse to Martius's method. This consists in mixing the dry impure chloride of iridium and ammonium with powdered cyanide of potassium, and fusing and then taking up with water the fused mass. After working some time with this method, with rather poor results, owing to the high heat required to bring the mass to fusion and the invariable decomposition of the newly formed double cyanides, resulting from the application of such a heat, I modified the method in several particulars. I found, on trying, that the black iridium oxide went very readily into solution in the fused cyanide of potassium. Taking, therefore, the double chloride of iridium and ammonium

and igniting it to transform it into the iridium oxide, I proceeded after the following manner:—

Covering the bottom of the crucible with a bed of powdered KCy, I then added a mixture of KCy and iridium oxide, and exposed it to the flame of the blast-lamp. The fusing cyanide takes up quite readily the metallic oxide, and is soon in calm fusion. A reduction still takes place, but by no means to the extent experienced before. This is occasioned by the strong heat which has to be applied to get the mass into full fusion. Another modification which I then made has some advantages over this just described. It is to bring a few pieces of KCy to full fusion, and then keeping it so, to add a previously prepared mixture of the iridium oxide and finely pulverised cyanide of potassium to it, in small quantities at a time. The advantage here is, that, when the KCy has once been brought to fusion, it can be kept there with a comparatively small flame, and the reduction of the double cyanides does not occur so readily. It is true, that adding the iridium so slowly, the compound is kept in the fused state longer. My experience, however, leads me to prefer this latter plan, and I generally used it as giving the largest yield. Birnbaum's method proper is now used. The solution of the double cyanides, filtered off from any unattacked iridium oxide, contains a tolerably large excess of free KCy. This is destroyed by adding dilute HCl. When neutral, a concentrated solution of copper vitriol is added. The violet-coloured precipitate of mixed double cyanides of iridium and platinum with copper is washed by decantation with boiling water. While suspended therein, a strong solution of caustic baryta is added. The copper is thrown down as brown oxide of copper, and the double cyanides of iridium and platinum with barium are formed, which remain in solution. When the fluid reacts distinctly alkaline, after a minute or so boiling, it is filtered off, and then CO_2 is passed through, until a neutral reaction is obtained. Filter off the precipitate of BaCO_3 , and then concentrate for crystallisation. The yellow platinum salt crystallises out first in small crystals, with a play of colours from yellow to blue, being similar in their dichroic effects to most of the other double cyanides of platinum. The iridium salt crystallises then in larger colourless prisms, which can be easily separated mechanically from the platinum crystals. The iridium crystals I ignited in a porcelain crucible, and having thus completely broken up the compound, drew out the baryta with boiling water. The iridium, after being well washed and ignited to completely oxidise it, was heated as before with aqua regia in a sealed tube to 200°C . The IrCl_4 solution obtained was again treated with absolute alcohol, and, on addition of KCl and NH_4Cl , the crystallised salts were obtained.

However, the compounds which were now formed were, contrary to my expectations, not the ethylen salts pure and alone, but there was a simultaneous formation of what appear to be several distinct compounds. Although in one preparation of ammonium salt analysed, the ethylen-protoclchloride-salt was isolated tolerably pure, yet, in the majority of the analyses, I had to do with a mixture difficult to separate even under the lens. The readiness with which these compounds decompose when subjected to re-crystallisation, even although one observes the precaution of keeping the solution distinctly acid, prevents any successful purifying that way. The preparation, therefore, had to be prepared for analysis by drying between bibulous paper, and then over H_2SO_4 or at 100° , according as I wished to determine the percentage of water or not. A certain amount of HCl from the acid solutions, therefore, adhering to the crystals, made the Cl determinations as a rule high. Still the results approximate sufficiently, these circumstances being taken into consideration, to the formulæ given, to show that several distinct compounds are here formed. My first crystallisation consisted of brownish-red octahedra, which when analysed gave in three Cl determinations 42.13 per cent, 42.07 per cent, and 42.09 per cent Cl, showing them

to be simple $\text{IrCl}_4(\text{KCl})_2$, of which the percentage of Cl is 42.08 per cent.

I next got a crystallisation of fine sharply-formed monoclinic crystals of a reddish-brown colour, which I think the analyses, although not perfectly conclusive, still go to show to be a new compound. Several different crystallisations of it were analysed. It could not always be entirely separated from the slight crust of decomposed KCl which separated out along with and among the crystals.

Preparation No. 1.—Large well-formed crystals, with but very little foreign matter adhering to the sides.

0.1567 grm. dried over H_2SO_4 lost by heating to 100°
0.0170 grm. = 10.85 per cent:

gave 0.0525 grm. metallic iridium = 33.50 per cent:
gave also 0.2275 grm. AgCl = 0.0563 grm. Cl = 35.92 per cent.

0.1610 grm. dried over H_2SO_4 lost by heating to 100°
0.0172 grm. = 10.68 per cent:

gave — Ir determination accidentally spoiled:
gave also 0.2320 grm. AgCl = 0.0574 grm. Cl = 35.65 per cent.

This we see at once cannot be any chloride of iridium and potassium. Its luminous flame, too, when burned, shows the same. Nor do the percentages agree with the simple potassic-ethylen iridium protochloride—

where the Ir = 48.45 per cent and Cl = 26.19 per cent.

If we reckon out the ratio of iridium to chlorine, we find it as 1 : 6, showing it to be an iridium chloride compound. The large per cent of loss on heating, the small Ir. and Cl per cents, when compared with double iridium and potassic chloride, and the luminous flame when burned, all go to show that an organic constituent must make the additional per cent. If we suppose now ethylen to enter here into the union with iridium chloride, hanging itself on, we can expect from the consideration of analogous compounds that 2 atoms of the bivalent radical C_2H_4 would join the atom PtCl_4 .

We would have on this supposition the formula

Now this formula with 3 atoms H_2O gives Ir = 32.93 per cent, Cl = 35.61 per cent, and with 2 atoms H_2O , Ir = 33.95 per cent, Cl = 36.71 per cent; anhydrous it gives Ir = 36.20 per cent and Cl = 39.14 per cent.

The large per cent of loss at 100° is not accounted for by $3\text{H}_2\text{O}$, which give only 0.03 per cent; but it is possible that in a compound where the organic constituent is so loosely connected with the rest, as must be the case here, a partial decomposition of the salt enters at 100° already.

In another preparation, also well crystallised, 0.1822 grm. dried at 100° :

gave 0.0678 grm. metallic iridium = 37.21 per cent;
gave also 0.3063 grm. AgCl = 0.0758 grm. Cl = 41.59 per cent.

In another preparation, indistinctly crystallised, 0.0502 grm. dried at 100° :

gave 0.0172 grm. metallic iridium = 34.26 per cent.

(Probably low from HCl mechanically admixed.)

In another preparation, also indistinctly crystallised, 0.3207 grm. dried at 100° :

gave 0.2125 grm. AgCl = 0.1268 grm. Cl = 39.53 per cent.

It will thus be seen the determinations, all things considered, agree close enough with the theoretical per cents of the formula to make it very probable. The want of enough sufficiently-well crystallised material prevented me from making an organic combustion which might settle it definitely.

Several individual crystals of the first crystallisation were very sharply and clearly formed, and I subjected them to examination under the microscope with a power

of about 50 diameters. The faces were clearly to be made out. They belong to the monoclinic system, and their prevailing habitus in crystallisation is a combination of the two lateral pinacoids with positive and negative pyramids accompanied by one macrodome on the ends. The faces observed in an examination of five distinct crystals were (according to Naumann)—

In considering the compounds of the iridium base with NH_4Cl , we find again a mixture of crystallised salts.

Preparation No. 1 consisted of sharply crystallised needles that looked almost black, and only by transmitted light showed a brownish-green colour. They were also monoclinic.

On analysis they prove, I think, to be the sought-for ethylen-iridium compound.

0.0713 grm. dried over H_2SO_4 lost on heating to 100°
0.0029 = 4.07 per cent:

gave 0.0850 grm. AgCl = 0.0210 grm. Cl = 29.49 per cent or 30.74 per cent of salt dried at 100° .

The iridium determination was made with magnesium, and was inaccurate as before.

The formula $\text{IrCl}_2\text{C}_2\text{H}_4\text{NH}_4\text{Cl} + \text{H}_2\text{O} = 367.5$ demands Cl = 28.98 per cent, $\text{H}_2\text{O} = 4.89$, or anhydrous 30.47 per cent Cl.

Preparation No. 2 was of much smaller needles and of lighter colour.

Analyses show it to be of very similar composition to the potassium salt described above.

0.1207 grm. dried at 100°C :

gave 0.0495 grm. metallic Ir. = 41.97 per cent:

gave also 0.2068 grm. AgCl = 0.0512 grm. Cl = 43.37 per cent.

$\text{IrCl}_4(\text{C}_2\text{H}_4)_2(\text{NH}_4\text{Cl})_2 = 0.502$ gives Ir = 39.25 per cent and Cl = 42.43 per cent, and supposing it to lose some of the C_2H_4 at 100° , as stated above,

would give Ir = 41.50 per cent and Cl = 44.94 per cent.

The other two preparations of the ammonium salt analysed appeared under the lens to be mixtures of the iridium protochloride-ethylen salt and the iridium chloride-ethylen salt given above.

The results were—

0.1322 grm. dried at 100° :

gave 0.0609 grm. metallic iridium = 46.07 per cent.

0.1715 grm. dried at 100° :

gave 0.0784 grm. metallic iridium = 46.95 per cent.

$\text{IrCl}_2(\text{C}_2\text{H}_4)(\text{NH}_4\text{Cl}) + \text{H}_2\text{O}$ gives Ir = 39.25 per cent.

$\text{IrCl}_4(\text{C}_2\text{H}_4)_2(\text{NH}_4\text{Cl})_2$ gives Ir = 23.61 per cent.

The existence of the base $\text{IrCl}_4(\text{C}_2\text{H}_4)_2$ I hope to settle definitely by renewed analyses of larger quantities.

While engaged with the preparation of the ethylen and iridium compound, the thought of the possibility of acetylen (C_2H_2) uniting with PtCl_2 or IrCl_2 led me to make some experiments in that direction. After a number of endeavours to form a platinum salt and analyses of the products (a detailed account of which is given in the original paper), I obtained negative results only. The existence of such a salt is highly improbable.—*American Journal of Science.*

ON A NEW FORM OF GAS APPARATUS.

By JOHN PARRY.

HAVING occasion to make daily analyses of the gases from the blast-furnace, finding the method of Bunsen very slow and tedious, and that Frankland and Ward's apparatus—though giving correct results—was unsuitable for daily use in the laboratory, I have designed the apparatus of which I enclose a sketch.

The measuring or gas tube, A, is enclosed in a glass cylinder filled with water, and dips into the mercury trough, B. The absorbing and eudiometer-tube, C, is connected with A by well-fitting elastic tubing of double thickness, firmly wired to the capillary glass tubing shown in the sketch.

The use of this apparatus hardly requires to be described. By alternately raising and lowering the mercury reservoir, R, both A and C are filled. The gas for analysis being then bubbled up into A, and measured with the usual precaution.

The liquid absorbent required is poured into the cup, G; R is lowered, M opened, thus drawing the test into C, a little being left in the cup to prevent admission of air.

The trap, N, is now opened, and the gas drawn into C; both M and N are to be kept closed while the gas is being subjected to the action of the absorbent. The latter must always be run into C as described, or it is drawn into the measuring-tube.

To clean C the gas is passed back into A, N is closed, and M opened, B lowered, and the mercury and absorbent allowed to flow out to about the level of L (see dotted line).

Unscrewing the nuts H and D, the lower part, W, is taken out, the test, &c., falling into a large basin placed under. While the mercury, &c., is falling down the tube C; water must be poured into the cup, G, for washing out traces of the absorbent.

The eudiometer-tube, C, is well washed with pure water, with the pipette, O (which consists only of an ordinary pipette joined to a long glass tube by a short piece of elastic tubing); it is evident the long tube may thus be conveniently passed up C, and the water blown through and up C, flowing down the sides of the tube into the basin.

The part W is made of iron or steel of the form shown, a plug of caoutchouc is firmly cemented into the short iron tube; the platina wires for explosions insulated in glass tubing, also the glass tube (wired to the elastic tubing, R, by which the reservoir, R, is raised and lowered) are passed air-tight through the caoutchouc plug.

The flanges, &c., W and L, should be well made with smooth true surfaces; a washer of caoutchouc is placed between the flanges, also the end of C presses down on the plug when the nuts H and D are screwed down.

The writer has used this apparatus for some time with very satisfactory results.

Analyses are rapidly and conveniently done; explosions are accomplished without difficulty, with far less trouble and risk than with the ordinary eudiometer; the gas for explosion may be expanded to any required extent by lowering R, and any risk of bursting C is thus entirely obviated.

Water may be substituted for mercury in the trough, B, but, of course, with less accurate results.

The eudiometer, C, may be supported by clamps attached to a long iron rod, and R raised or lowered by a pulley.

The writer attaches the eudiometer to a board to which a pulley is fixed, as shown by the dotted lines.

I am also much indebted to my assistant, Mr. James Needham, for his aid in arranging the details of the apparatus.

ANCIENT JEWISH GLASS.

By DUGALD CAMPBELL, F.C.S.

HAVING recently analysed some ancient glass which I obtained from Mr. Bessant, secretary to the "Palestine Exploration Fund," and which, that gentleman writes, "Is all from shafts round the Temple, and found at depths varying from 20 to 80 feet," and as its history is truly interesting and its composition is somewhat curious, an analysis, I trust, may not be considered out of place in your valuable journal.

The sample of glass furnished me weighed altogether about 3 ounces, and consisted of a number of small pieces, many of which in parts had undergone a change both in structure and colour by time and exposure.

The portion selected for analysis was from pieces which appeared to me to have undergone the least if any change, and the results were as follows, in 100 parts:—

Silica	69.30
Lime	8.50
Magnesia	0.55
Soda	13.79
Potash	1.49
Alumina	3.20
Oxide of iron (FeO ₃)	2.00
Oxide of antimony	0.29
Oxide of lead	trace
Phosphoric acid	0.80
Loss in analysis	0.08

The specific gravity of the glass is 2.430.

7, Quality Court, Chancery Lane, London,

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 7th, 1871.

Professor FRANKLAND, F.R.S., President, in the Chair.

WHEN the minutes of the Society had been read and confirmed, Mr. James L. Shuter was formally admitted a member, and the President announced that Mr. Cassiot had presented to the Society a greatly enlarged photograph of Daniell and Faraday.

The names of the following gentlemen were read for the first time:—Julian Louis Vanderstraeten, John Millar Thompson, Charles W. Vincent, Robert Barton, David Watson, William Thompson, William Forster, Henry James Helm, Thomas W. Fletcher, George Thomas Glover, and Thomas Eltoft.

For the third time—Charles Thomas, Benjamin Tanner, Hugh Paterson, Frederick Hicks, George Joseph Warner, Samuel William Moore, William John Wilson, William Gray, Robert Irvine, Reginald C. Woodcock, and Donald Munroe. After a ballot had been taken, these gentlemen were declared by the President to be duly elected.

Dr. J. H. GLADSTONE, F.R.S., then read a paper "On Essential Oils," Part II. The following is a short

abstract of this valuable and laborious communication, which is the continuation of one laid before the Society eight years ago. The first group of oils described includes—(1). That of citrin from the leaves of the lemon tree, which consists principally of a liquid boiling at 166° to 168° , sp. gr. 0.8459; refractive index for the line A 1.4680 , and dispersion 0.273 . (2). Lign aloes: a colourless oil having a pleasant odour, the greater part of which comes over at about 200° . (3). Pimento, from the seeds of *Myrtus pimento*, the greater portion of which distills at 243° , and is found to be entirely soluble in potash solution. It has a sp. gr. of 1.0436 , refractive index for A 1.5287 ; dispersion about 0.416 ; and in other respects agrees with eugenic acid, so that the oil of pimento seems to differ from oil of cloves only in the hydrocarbon that is mixed with the eugenic acid. (4). Oil of Villvert, which is composed chiefly of an oil boiling at 280° to 283° ; the action of sodium, however, showed that this was not homogeneous, but a mixture of two bodies.

The hydrocarbons from essential oils may be divided into three polymeric groups having the general formulae $C_{10}H_{16}$, $C_{15}H_{24}$, and $C_{20}H_{32}$. The first group, $C_{10}H_{16}$, represents the greater number of these hydrocarbons, turpentine, orange, carraway, and more than twenty others. The second, $C_{15}H_{24}$, those from cloves, rosewood, cubeb, calamus, cascarilla, and patchouli, whilst the third is represented by colophene. That there is a broad line of demarcation between these three groups may be seen by comparing their physical properties set down in the following table, which also shows that the middle group is intermediate in its properties between the C_{10} and the C_{20} groups:—

	I. $C_{10}H_{16}$	II. $C_{15}H_{24}$	III. $C_{20}H_{32}$
Vapour density..	4.7	7.1	—
Specific gravity	0.846—0.880	0.904—0.927	0.939
Refractive index for A	1.457—1.467	1.488—1.497	1.5084
Dispersion..	about 0.027	about 0.029	0.031
Sensitiveness	about 48	about 43	41
Boiling-point	160° — 176°	249° — 260°	315°

Many of the essential oils are mixtures of a hydrocarbon with a compound containing oxygen, of which but few have hitherto been carefully examined. Those obtained from citronella and from wormwood the author calls citronellol and absinthol respectively: they both have the composition $C_{10}H_{16}O$, the most remarkable point of difference between them being in their refraction equivalents; that of absinthol being 74.5 , which agrees closely with the theoretical for $C_{10}H_{16}O$, while citronellol has 79.3 or 79.8 for its equivalent, a discrepancy almost the same as that found throughout the great phenyl group. Besides these he has examined cajuputol from oil of cajuput, and also the two carvols from oil of carraway and oil of dill. These appear to be identical and not merely isomeric, and are remarkable for forming a crystalline compound with sulphuretted hydrogen having the composition $(C_{10}H_{14}O)_2H_2S$. The physical properties of menthol from spear mint, myristicole from nutmeg, and hydride of cumanyl from cassia, have likewise been examined; the latter has the enormous refraction of 1.6045 for the line A, and its refraction equivalent is also very abnormal.

The PRESIDENT said that the paper which Dr. Gladstone had communicated to the Society was one of great importance, since these physical qualities were facts which would remain unalterable however much our views as to the theory of their constitution might change, and although no one admired this class of investigation more than he did, he might also be allowed to speak a word in favour of certain chemical reactions which might, perhaps, enable us to relegate these hydrocarbons to their proper families, such as the action of chlorine or bromine on them. He should like to elicit from the author if he had tried any such reaction, so as to distinguish, for example, whether they were hydrides or radicals.

Dr. GLADSTONE said that bromine and chloride derivatives had been prepared, but that, in the cases he had tried, the result had been unsatisfactory.

Dr. WRIGHT asked whether his researches had led the author to consider the hydrocarbons as isomeric in the same way that the butylic hydrides are, or was it possible that many of these hydrocarbons might be identical, the difference in their properties being due to accidental impurities.

Dr. GLADSTONE replied that these oils were distinguished in some cases chiefly by their optical properties, and in others by their odour; citronellol was distinguished from absinthol by the former, having a considerably higher refractive equivalent than the theoretical, like that found in compounds throughout the great phenyl group; and again, the carvol from dill and the carvol from carraway were considered to be identical and not isomeric, from having the same odour; the same might be said of the eugenic acid from pimento and from cloves; identity of odour alone, however, is not sufficient to establish the identity of the hydrocarbons.

Dr. WRIGHT suggested that the odour might be due to a chemical change which the substance undergoes in the presence of oxygen and in contact with the mucous membrane of the nose. It was well-known that hydrocarbons which had been recently distilled over sodium had a less powerful odour than they had after being exposed for some time to the air.

Professor A. H. CHURCH would like to refer to the very interesting sulphur compound, $(C_{10}H_{14}O)_2H_2S$, in which an oxidised oil was united with sulphuretted hydrogen. Some eight or nine years ago he had described tasmanite, a resin found in a shale from Tasmania, which contained oxygen and sulphur in the same relative proportions as the above-mentioned compound. This resin, when treated with sulphuric acid, evolved sulphuretted hydrogen, so that the sulphur was in organic union with it, and not like the sulphur found in coal. In another fossil resin, dysodile, which he had examined the sulphur and oxygen only approximated to that ratio, but then it was not pure.

Dr. H. E. ARMSTRONG then read a paper entitled "*Observations on Nitrochlorophenols*," No. III. This communication comprises the experiments made to discover the relation between the dinitrochlorophenol melting at 110° to 111° and its isomers and the nitrodichlorophenols. For this purpose the author first converted dinitrophenol into dinitrochlorophenol by treating it with chlorine in the presence of antimony pentachloride. The compound melts at 110° to 111° , and is identical in every respect with that obtained by the nitration of dichlorophenolparasulphonic acid. The nitro-compound was converted into the amidonitrochlorophenol in the usual way; this crystallises in long slender brass-yellow needles, which lose their water of crystallisation at 100° and melt at 140° . The chlorination of the orthonitrophenol was effected by the direct action of chlorine, but the product was somewhat difficult to purify. When this is done, however, the chloronitrophenol crystallises in white silky needles, which melt at 109° to 110° , and would seem to be identical with that obtained by Faust from dinitrochlorophenol. By the action of fuming sulphuric acid on dichlorophenol an acid was obtained, the potassium salt of which, when treated with nitric acid, gave a dinitrochlorophenol melting at 103° , apparently identical with that obtained by Stenhouse, by the action of chloride of iodine on picric acid; in most of its properties it bears a very strong resemblance to the isomeric phenol melting at 110° , the great difference being that all the salts of the former are orange-red, whilst those of the latter are yellow.

In reply to an observation of the President, Dr. Armstrong illustrated the possible constitution of some of the nitrochlorophenols according to Kekulé's view of the structure of benzol.

The meeting was then adjourned until Thursday, December 21.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, November 28th, 1871.

J. P. JOULE, D.C.L., LL.D., F.R.S., Vice-President, in the Chair.

MR. RICHARD SAMUEL DALE, B.A., was elected an Ordinary Member of the Society.

"*Encke's Comet, and the Supposed Resisting Medium,*" by Professor W. STANLEY JEVONS, M.A.

The observed regular diminution of period of Encke's comet is still, I believe, an unexplained phenomenon for which it is necessary to invent a special hypothesis, a *Deus ex machina*, in the shape of an imaginary resisting medium. I cannot be sure that the suggestion I am about to make has not already been made, but I have never happened to meet with it; and therefore I venture to point out how it seems likely that the retardation of the comet may be reconciled with known physical laws.

It is asserted by Mr. R. A. Proctor, Professor Osborne Reynolds, and possibly others, that comets owe many of their peculiar phenomena to electric action. I need not enter upon any conjectures as to the exact nature of the electric disturbance, and I do not adopt any one theory of cometary constitution more than another. I merely point out that if the approach of a comet to the sun causes the development of electricity arising from the comet's motion, a certain resistance is at once accounted for. Wherever there is an electric current some heat will be produced and sooner or later radiated into space, so that the comet in each revolution will lose a small portion of its total energy. In the experiments of Arago, Joule, and Foucault the conversion of mechanical energy into heat by the motion of a metallic body in the neighbourhood of a magnet was made perfectly manifest. If then there is any magnetic relation whatever between the sun and comet, the latter will certainly experience resistance.

The question is thus resolved into one concerning the probability that a comet would experience electric disturbance in approaching the sun. On this point we have the evidence now existing that there is a close magnetic relation between the sun and planets. If, as is generally believed, the sun-spot periods depend on the motions of the planets, a small fraction of the planetary energy must be expended. I find, indeed, that a very brief remark to this effect was given in the memoir of the original discoverers of the relation, namely—Messrs. Warren de la Rue, Balfour Stewart, and B. Loewy. At p. 45 of their "*Researches on Solar Physics*" they add a small note to the following effect:—"It is, however, a possible enquiry whether these phenomena do not imply a certain loss of motion in the influencing planets." As I conceive, no doubt can exist that periodic disturbances depending upon the motions of bodies must cause a certain dissipation of their energy, for if stationary the constant radiation of the sun could not produce any periodic changes, unless the sun were itself variable. Is there not, then, a reasonable probability that the light of the aurora represents an almost infinitesimal fraction of the earth's energy, and that in like manner the light of Encke's comet represents a far larger fraction of its energy? It is also worthy of notice that the tail of a comet is usually developed most largely at those parts of its orbit where the rate of approach or recess is most rapid, and where the electric disturbance would be correspondingly intense.

I do not, of course, deny that the resisting medium may nevertheless exist, or may by other observations or experiments be made manifest. But I hold that so long as other physical causes can be pointed out which might produce the same effect, it is quite unphilosophical to resort to a special hypothesis. Encke's comet ought not to be quoted as evidence of the existence of such a medium until electric

disturbance is shown by calculation to be insufficient to account for the observed diminution of period.

"*On Cometary Phenomena,*" by Professor OSBORNE REYNOLDS, M.A.

In all comets which have been observed through powerful telescopes there is an action going on which appears to be the result of evaporation. Jets of something like vapour are seen to issue from what is supposed to be a solid nucleus on that side which is towards the sun.

No such signs of evaporation are observed on the planets, nor is there any phenomenon that we are aware of which can be compared with this taking place on our earth. At first sight it seems strange that the sun should act to more effect on such small bodies as comets than it does on the larger bodies, even when the latter are nearer to it than the former. When, however, we come to look closer, I think good reason may be given for this; and I think that the difference of evaporation on the earth and on a comet may probably be the cause of electrical phenomena existing on the latter which certainly do not exist on the earth, and that the relation between the motion of the comet and the evaporation which might be expected to take place is precisely that which is observed between the motion and those appearances which I would explain on an electrical hypothesis.

The first thing to be done is to take notice of the following facts:—

(1.) Comets move in very eccentric orbits, whereas the planets move in orbits nearly circular.

(2.) Comets are supposed to be much smaller than the planets.

(3.) All the heat received by a body from the sun must be expended in one or other of the following ways:—

I. By radiation from the body.

II. By evaporating the materials.

III. Producing chemical change in these materials, or in electrical separation, &c.

That spent in the third method may be considered small.

Thus the heat which a body receives = heat radiated + heat spent in evaporation (1).

and

$$\frac{\text{heat radiated}}{\text{heat received}} = (\text{some constant}) \times \frac{\text{temperature of body (2)}}{(\text{distance of sun})^2}$$

Now, the temperature at which any given material, say water, would evaporate would be much lower on a comet than on a planet, on account of the comet being so much smaller. For we may assume that there is a limit to the pressure which an atmosphere of vapour of unlimited extent can exert on the materials of the body it envelopes; then the limit of the temperature of the body will be that which will evaporate the material of the body under this pressure. It is clear that if there be such a limit it must increase very rapidly with the mass of the solid body, and hence that it would be much higher in the case of a planet than in that of a comet. This temperature may be called that of permanent evaporation, for as long as it was maintained the body would continue to evaporate; therefore the temperature of permanent evaporation of the planet would be much greater than that of the comet. That is, from equation (2.) the ratio of the heat radiated away to that received would be much less in the case of the comet than in the case of the planet, leaving, by equation (1.) a greater ratio for evaporation in the former than in the latter.

Now it is clear that our earth is well out of reach of this permanent evaporation; for the temperature at the equator is much less than 212° F., which is the boiling-point of water, its most volatile substance; and we may assume that the same is the case with all the other planets. If, however, the earth's atmosphere were removed, then evaporation would go on until there was another atmosphere formed which would hold the liquid in check. If, however, the earth had no attraction for vapour, or only a very slight one, then it would go on evaporating, in the

first place, until all the water was ice, and then it would spend all the heat it got from the sun in vapour. This, according to Sir J. Herschel's rate, is sufficient to melt ice just enough to reduce the diameter of the earth by an inch in about $4\frac{1}{2}$ hours, and if it had to evaporate the water as well as melt the ice it would evaporate about 1 inch in 130 hours. Now, although this is a purely imaginary condition with regard to the earth, yet it must exist in the case of a small body like a comet, that is to say, there would be no liquid on the comet even when evaporation was going on, and, when the comet was near enough the sun, permanent evaporation would go on, which would only be ended by the comet removing itself, or by the exhaustion of the volatile material. This latter would take place supposing a comet should change its orbit, when near the sun, into a circular orbit, like a planet or meteorite. Even in the case of a periodic comet, there must be some exhaustion of the volatile materials. During the two hours in which the comet of 1843 was within close approximation to the sun, if the comet had been made of ice covered with lamp-black it would have received the heat of 47,000 suns according to Sir J. Herschel's computation. This would have evaporated the ice at the rate of 55 feet per hour on that side next the sun, or 13 feet over the whole comet. But in fact, owing to the protection of its atmosphere and imperfect absorbing power, it would have been much less than this, that is to say, the diameter of the comet would not have been reduced 10 feet. However, it may be that all the material evaporated is not lost. For, from the way in which comets approach and recede from the sun, it is probable that part of their orbit lies without, and part within, the range of permanent evaporation. Hence during part of their motion, when they are distant from the sun, condensation will be going on if there is anything to condense. This agrees well with the observed fact that a periodic comet makes less and less display each revolution. There the heat acts on the surface of the comet so that the less volatile substances would form a skin over the softer ones, through which the heat would have to pass, and through which the steam would have to force its way in jets.

Now such jets as these would act the same part as the jets in Armstrong's hydro-electrical machine, and the vapour which emerged would be charged with either positive or negative electricity, as the case might be, the solid being charged with electricity of the opposite kind.

The vapour, as it formed an atmosphere round the nucleus, would then discharge some of the electricity back. This would cause those portions which were nearest the nucleus to be bright (self-luminous), brighter than the more distant. Although the variations in temperature would be slight, yet as the atmosphere moved outwards from the nucleus there would be expansion, and consequently condensation; hence the outside of the coma might be illuminated by the direct rays of the sun, or we might have several bands of condensed vapour so illuminated, as suggested by Sir J. Herschel. On the other hand, I think this illumination may be due, at least in part, to the electric action between the matter of the comet and matter previously in space. This point will probably be settled by Mr. Huggins when the next large comet makes its appearance.

The period of greatest display is not reached till after the comet has passed its perihelion, and the tail is visible for much longer after this than it was before it. Now, if we suppose the comet to be made up of hard and volatile substances, owing to the heat absorbed by the hard substances the evaporation would lag somewhat behind the position of the comet, and consequently be greatest after it had passed its perihelion distance, just as a thick retort will continue to boil after the lamp has been removed. Hence we see that, if the evaporation causes electrical separation in the comet, this will be at its maximum just when the display is observed to be at a maximum.

This communication is not intended as an alteration of

the views which I expressed in a former communication, but as an extension of those views, for I formerly advanced no hypothesis as to the possible cause of the electricity. Also, with regard to the formation of tails, I wish to add somewhat to my former remarks. Professor Norton has shown that the primary tail of Donati's comet might have been formed by matter emitted by the comet, and repelled by the sun with a force equal to from 0.75 to 0.55, the attraction of the sun for ordinary matter; the matter repelled with 0.55 forming the following edge, that with 0.75 the leading edge of this tail. Professor Norton suggests that these forces may be electrical or magnetic.

Accepting Professor Norton's calculations as correct, it is certain that if, for some cause or other, the sun repelled negative electricity, and there were two streams of electrified matter leaving the comet, charged in the ratio of 0.75 to 0.55, these would be repelled in the ratio he wants; at the same time I do not think he has sufficiently taken into account the repulsion one stream would have on the other.

Professor Norton does not suggest an explanation of the straight tails seen with most comets as primary or secondary tails. These I maintain can only be explained on the supposition that there is matter in space in the form of gas, and that the comet causes it to be electrically illuminated by a brush, as I stated in my former communication.

Again, if the tail of the comet be electricity of one kind (say negative), leaving the comet never to return, then the comet must leave the neighbourhood of the sun with a charge of positive electricity, which, as it gets further from the sun and evaporation becomes feeble, will in time overpower the negative electricity in the atmosphere, which will then be attracted by the sun instead of repelled, and if the comet has any tail it will now turn away from the sun; in which condition it will probably remain until its approach to our sun, or some other star, again cause it to become negative and turn round. In this case a periodic comet would turn its tail round at definite points in its orbit, and, owing to the lagging of the symmetry of the comet's appearance in its orbit, the point of turning will be nearer to the sun on its return than on its departure. Now it seems, from a remark of Professor Airy, that comets, when first seen, often have their tails before them, and that such is the case with Encke's comet now visible.

GLASGOW PHILOSOPHICAL SOCIETY: (CHEMICAL SECTION).

Ordinary Meeting, December 4th, 1871.

Dr. WALLACE, F.R.S.E., in the Chair.

Dr. JOHN CLARK read a paper on "*The Analysis of Chrome Ores, and a New Method of Estimating the Oxide of Chromium.*" He first referred to the discrepancies which Dr. Genth, in 1862, had noticed between his own analyses of such ores and those of English chemists. Discordant results still exist, and the consumers of chrome ore complain that in the manufacture of bichromate of potash there is a loss of oxide of chromium which they can only account for on the supposition that the chemist reports too high a result. Such complaints are not altogether unfounded, and the author considered that, while some discrepancies may be due to differences in the samples, the greater number must be due to the inexperience of the analysts and to the difficulty of obtaining correct results by the ordinary methods of analysis. Dr. Genth recognised the impossibility of obtaining, by washing alone, an oxide of chromium precipitate perfectly free from alkali after fusing the ore with bisulphate of potash, and he recommended that, before weighing, the ignited precipitate should be boiled with water containing

sulphurous acid to reduce the chromate which had been formed, and that the resulting oxide should be precipitated with ammonia. By this means the weight of the precipitate of oxide of chromium is greatly reduced.

Dr. Clark said he had never obtained a perfectly pure oxide by this method, and instead of boiling with water containing sulphurous acid, he had been in the habit of using dilute acetic acid, and estimating chromic acid thus removed with the diluted solution of the double sulphate of ammonium and iron of known strength. The oxide of chromium, in the form of chromate, usually amounts, even in the most carefully washed precipitates, to 0.76 per cent. The author referred to the process of M. Clouet, manufacturer of bichromate of potash, Havre, as one which gives very good results. This consists in fusing pulverised chrome ore with from five to six times its weight of pure carbonate of soda in a platinum crucible for five or six hours at a bright red heat, without the addition of any oxidising agent, reducing the purified chromic acid formed with alcohol in presence of hydrochloric acid, and precipitating the oxide of chromium with ammonia. But although this process yields the correct amount of oxide of chromium, it is not well adapted for the laboratory on account of the length of time required for the complete oxidation of the oxide of chromium in the ore.

Dr. Clark stated that perfectly accurate results might be obtained by the following process, which is both simple and expeditious:—25 grains of the finely-pulverised ore are intimately mixed with 5 parts of hydrate of sodium and 3 parts of calcined magnesia, and the mixture is exposed in a platinum crucible in a Bunsen flame for $\frac{3}{4}$ of an hour, with the lid on. Oxidation at once takes place under the influence of the hydrate of sodium and magnesia, and it is practically complete in less than an hour. The crucible with its contents is then placed in a basin containing water, the contents being washed out with water as far as possible, and the operation completed by using dilute sulphuric acid quite free from nitric acid. An additional quantity of dilute sulphuric acid is added and then the whole is heated. Everything will dissolve, except, perhaps, a few flakes of silica. To the clear yellow solution is added a weighed quantity of double sulphate of iron and ammonium of known strength, and more than is sufficient for the reduction of the chromic acid. The excess of unoxidised iron is then estimated with a weak standard solution of bichromate of potash, and the amount of oxide of chromium in the ore calculated from the quantity of iron oxidised. The results obtained by Dr. Clark by the process now described seldom vary 0.2 per cent. The process has been submitted to a number of chemists, including the Director of the School of Mines in St. Petersburg, who has not only expressed a very favourable opinion of it, but who has also adopted it in the testing of the Russian ores.

Dr. Clark gave a brief digest of M. Clouet's paper (*Annales de Chim. et Phys.*), and stated that he had never been able by Clouet's process to remove the alumina completely soluble in water by fusion with carbonate of sodium, and that he had always found a considerable proportion of the alumina in the precipitate, which M. Clouet regards as pure oxide of iron. He also stated that in the many analyses which he had made of chrome ores he had never found the composition to agree with any of the formulæ given by M. Clouet; still he did not say that the protoxide of iron and the sesquioxide of chromium did not exist in definite proportions. However, if they did exist in definite proportions, it must be necessary to frame other formulæ to represent the relationship of the two compounds in addition to those mentioned by M. Clouet.

A short discussion followed in which Dr. Wallace and Dr. Thorpe took part, the former referring to the isomorphous character of magnesia and protoxide of iron, and the sesquioxides of chromium and iron, as a circumstance which might not have been observed by Clouet in his analyses and in framing his formulæ.

Dr. T. E. THORPE, F.R.S.E. made a short oral communication on "A Method of Taking Specific Gravities." He exhibited and described an exceedingly neat and ingenious apparatus which he had devised for taking the specific gravities of certain volatile compounds, more especially the oxychlorides, such as—

By means of the apparatus Dr. Thorpe stated that he had been able to obtain the following results in respect of oxychloride of phosphorus, taking three operations:—7.47062, 7.47014, and 7.47019; while oxychloride of vanadium gave the following results:—8.06408, 8.06381, and 8.06450. He explained that the instrument might, with more or less structural modification, be applied to other uses, such, for instance, as determining expansion coefficients; as a pipette for brominating hydrocarbons, and as a specific gravity where volatile hydrocarbons are concerned.

The apparatus excited much interest among the members, and was greatly admired on account of its ingenious arrangements.

CORRESPONDENCE.

SMOKE DRAINAGE.

To the Editor of the Chemical News.

SIR,—I have to thank you for naming the fact that the suggestion of the Rev. B. W. Gibsone is merely a repetition of that of which I gave a detailed statement with all the data needful for proving its practicability in the paper read before Manchester Literary and Philosophical Society, and published by me in 1857. A copy of this pamphlet I shall be most happy to transmit to Mr. Gibsone on his furnishing me with his address. I am sorry I missed seeing his letter in the *Times*, else I should have referred to it sooner. I beg, however, to demur most decidedly to your statement that I had found difficulty in obtaining sufficient draught, &c., to effect the object.

Where the matter has been at all attempted, I believe there has been no difficulty of the sort found to exist, and, had Mr. Waterhouse's design for the new Law Courts been adopted, as I believe it ought, you would have had the scheme in its integrity carried out in that building with 1000 fires and ventilating flues turned into the sewerage below, and carried up in one shaft 300 feet high. Anyone who will go over the calculations in my pamphlet will see that the only practical difficulty is the expense of re-constructing our flues and sewerage. I may say that the strong language I used in 1857 against the London sewage scheme then only contemplated, I fully endorse now it is completed.—I am, &c.,

PETER SPENCE.

Pendleton Alum Works, Manchester,
December 11, 1871.

MISCELLANEOUS.

The Rupture of Iron Wire by a Blow.—At the last meeting of the Manchester Literary and Philosophical Society, Mr. John Hopkinson, B.A., D.Sc., detailed some experiments on this subject, the results of which are—1st. That if any physical cause increase the tenacity of wire, but increase the product of its elasticity and linear density in a more than duplicate ratio, it will render it more liable to break under a blow. 2nd. That the breaking of wire under a blow depends intimately on the length of the wire, its support, and the method of applying the blow. 3rd. That in cases such as surges on chains, &c., the effect depends more on the velocity than on the momentum or *vis viva* of the surge. 4th. That it is very rash to generalise from observations on the breaking of structures by a blow in one case to others even nearly allied, without carefully considering all the details.

CHEMICAL NOTICES FROM FOREIGN
SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, November 13, 1871.

This number opens with a brief but well deserved eulogium on the late illustrious Sir Roderick Impey Murchison, who was one of the Foreign Associates of this eminent scientific institution. Due honour is done to the memory of the celebrated deceased *savant* by his eminent *confrère*, the eloquent M. Dumas.

This number contains, in addition to several papers relating strictly to other departments of science, the following papers relating to chemistry:—

Thermal Researches Relating to Crystalline Dissociation.—P. A. Favre and C. A. Valsen.—The contents of this very lengthy essay are not suited for useful reproduction, owing to the fact that it would require the reproduction of a very lengthy series of tabulated forms exhibiting results of experiments.

Salant.—E. P. Bérard.—Under the name of salant, also *salan* and *salobré*, is understood, in those Departments of France which border on the Mediterranean, a light saline crust found on the soil of certain portions of the localities alluded to, which soil is almost entirely sterile and unfit for any plants to grow on. The author has made some researches on this matter, and paid more particular attention to the alluvial deposit met with near Agde (Département de l'Hérault). It appears that this salant is chiefly composed of chloride of sodium and the sulphates of lime and magnesia. The contents of this paper are, however, chiefly of local interest only.

Formation of Precipitates.—Dr. Berthelot.—The continuation of the exhaustive essay on this subject, this portion treating on the separation between the acid and the base of the salts.

Most Economical Arrangement to be Given to Galvanic Elements in Reference to their Polar Electrodes.—Th. du Moocel.

November 20, 1871.

This number contains the following papers more especially relating to chemistry:—

Thermal Researches on Electrolysis.—P. A. Favre.—The continuation of this very lengthy and exhaustive essay.

Velocity of Sound in Sonorous Pipes.—J. Bourget.—An algebraico-physical essay; an observation also applicable to the following paper:—

Transversal Vibrations of Strings and Thin Laminæ.—E. Gripon.

New Phenomenon of Phosphorescence Produced by Frictional Electricity.—Dr. Alvergniat.—A vacuum is first made into glass tubes about 45 centimetres in length. After the introduction into these tubes of a small quantity of either chloride or bromide of silicon, the pressure inside these tubes having been reduced to 12 or 15 millims., the same are sealed by means of the glass-blower's lamp. When such tubes are next rubbed with a piece of silk, there appears inside the tubes a bright luminous flash, which exhibits a rose colour with the chloride, and a yellowish green colour with the bromide, of silicon. Only when a more perfect vacuum is made in these tubes the induction spark produces a luminous phenomenon in them when the spark passes through, but then the phosphorescence by friction entirely disappears.

Continuation of the Essay on the Formation of Precipitates.—Dr. Berthelot.—This portion treats on the change which occurs in the state of aggregation.

Conversion of Albuminoid Matter into Urea by the Action of Permanganate of Potassa.—E. Ritter.—The contents of this paper contain the record of a series of experiments made by the author simply with the view to ascertain whether the researches of Dr. Béchamp on this subject, which have been repeatedly (even very recently by Dr. O. Loew) contradicted and declared to be wrong, are or are not correct. The author of this paper states that, by correctly following the directions given by Dr. Béchamp, he (Dr. Ritter) has perfectly succeeded in converting albumen, fibrin, and gluten into urea, by the action of the salt alluded to, but the quantities of urea so obtained are very small, as may be inferred from the following data:—30 grms. of albumen yielded 0.09 grm. of urea; fibrin, 0.07 grm.; gluten, from 0.21 to 0.31 grm.

This number also contains several original papers relating to physical geography, geology, astronomy, meteorology, and natural history.

The American Journal of Science and Arts, November, 1871.

This number contains the following original papers relating to chemistry and collateral sciences:—

On Some Phenomena of Binocular Vision.—J. Leconte.—The sixth portion of this lengthy essay, illustrated by several woodcuts.

Variations of the Temperature of the Human Body.—Dr. B. F. Craig.—An important physiological paper, recording a series of experiments.

Precise Geographical Position of the Large Masses of Meteoric Iron in North Mexico, with the Description of a New Mass—the San Gregorio Meteorite.—J. Lawrence Smith.—In the introduction to this paper, the author relates what has become known about the meteorites of North Mexico by the labours of the Boundary Commission. The immense mass of meteoric iron—the San Gregorio meteorite—is situated on the western border of the Mexican desert. Its shape (illustrated by a woodcut in the original) bears some likeness to that of a blacksmith's anvil. Its greatest length is 6 feet 6 inches; it is 5 feet 6 inches high, and 4 feet thick at its base. On one part of its surface "1821" is cut with a chisel, and above this date is the following inscription:—"Solo dios con su poder esto fierro destruerá, por que el con mondo non habra quien lo puedo deshechar" (Only gods can have the power to break up this mass of iron, for there is no body on earth who can break it to pieces). The weight of this mass is nearly 5 tons; it lies near to the spot where it has fallen, but nothing is further known of its history. The author has examined a small detached specimen of this stone, which is of the softer meteoric iron (sp. gr. = 7.84). Chemical composition per cent:—Iron, 95.01; nickel, 4.22; cobalt, 0.51; copper, minute traces; phosphorus, 0.08. The Mexican desert has an extension of 400 miles from east to west, and 500 miles from north to south = an area of 200,000 square miles. The United Kingdom has an area of 121,518 square miles.

Iridium Compounds Analogous to Ethylen and Protochloride of Platinum Salts.—S. P. Sadler.—Reproduced in present number.

The Paragenesis and Derivation of Copper and its Associates on Lake Superior.—K. Rumpely.—The continuation of a lengthy essay on this subject.

Observations on the Colour of Fluorescent Solutions.—Dr. H. Morton.

As is usual, this number contains some excellent original papers relating to natural history, astronomy, geology, and botany.

Zeitschrift für Chemie von Brilstein, No. 12, 1871.

This number only contains the following original paper:—

On Dibromo-Benzol-Sulpho Acid.—A. Wblz.—In the introduction to this paper, the author briefly refers to the researches of Dr. R. D. Williams on this same subject (see *CHEMICAL NEWS*, vol. xxiv., p. 193), stating that the last-named author's results of experiments do not materially differ from those obtained by himself. The dibromo-benzol-sulpho acid fuses at between 97° and 98°. The following salts of this acid are briefly described:—Barium salt, $(C_6H_3Br_2SO_3O)_2Ba$, a beautiful crystalline substance, difficultly soluble in cold, readily so in hot water; potassium salt—

obtained by double decomposition from the baryta salt, is soluble in water and in alcohol; calcium salt, $(C_6H_3Br_2SO_3O)_2Ca + 9H_2O$, a crystalline efflorescent salt, readily soluble in water and alcohol; lead salt, not very soluble in water; copper salt, a very rapidly efflorescing green-coloured salt, very soluble in water; ammonium salt—

a needle-shaped crystalline salt, very soluble in water. The acid alluded to is isomeric, not identical, with that obtained many years ago by Schmitt.

Le Moniteur Scientifique Quesneville, Nos. 357 and 358 (double number), November 1 and 15, 1871.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Historical Notice on the Labours which have Led to the Synthesis of Indigotine.—A. Rosenstiehl.—We regret that the contents of this very excellent essay do not admit of any useful abstraction.

Constitution of Milk and of Blood.—Dr. J. Dumas.—This paper was read last summer at Genève, but it is impossible to give an abstract without detracting from the merits of the essay.

Observations on the Alteration of Well-Water by the Proximity of Burial-Grounds.—J. Lefort.—The contents of this paper bear more especially upon the effect of a decree, dated March 7, 1868, whereby it has been enjoined that no wells shall be bored or dug out at a less distance than 100 metres in all directions from any burial-ground. The author, having found that not only in many country villages but also in several towns this regulation has not been observed, has made some experiments on the water of a well at Saint Didier (Département de l'Allier). This locality is situated on an alluvial soil; this water is used for drinking purposes by the parish priest and a portion of the inhabitants, and, on examination, the author found it to contain not only a large proportion of ammoniacal salts but also, on evaporation, to leave a very large quantity of a dark-coloured organic matter mixed with carbonated salts, which, on being mixed with some hydrochloric acid, gave off an offensive carbonic acid gas, the smell being somewhat akin to a mixture of a concentrated solution of glue and butyric acid. The well is very deep, and the water is quite clear and bright, but exhibits, especially in summer time, a very rapid taste, while, in the warm season of the year, it rapidly becomes putrid. The author comes to the conclusion that, in any soil, a well dug at the

distance of 100 metres from either burial-grounds or battle-fields is quite useless to protect the water of even deep wells from becoming so contaminated with organic and other injurious matter as to make it imperatively necessary to make new and sound regulations on this subject, so as to avoid wells (for obtaining potable water for domestic use) being sunk without a stringent inquiry as to where the water comes from, and through what strata of soil it may have to pass.

Remarks on Dr. A. Taylor's Process for Detecting Blood Stains.—J. Lefort.—A medico-forensic essay of value.

Practical Instruction in Beet-Root Sugar Preparation.—Dr. Vivien.—An excellent and clearly written paper on the so-called boiling (really evaporation of water from a saccharine juice) of sugar.

Boiling of Food at a Temperature below 100°.—Dr. Jeannel.—The contents of this lengthy essay record the results of a series of experiments, from which it appears that food (meat as well as vegetables) boiled at 95° is more nutritious and of better flavour than when boiled at or above 100°. The author illustrates this point by what takes place in mountain localities (every 100 metres' rise above sea level make a difference of 1° C. less in the boiling-point of water); as, for instance, at Potosi (Bolivia), at 4061 metres above sea level, and an average barometer reading of 454 m.m., the water boils at 86.2°; at Mexico, 2277 metres above sea level, 569 m.m. barometer, water boils at 92.1°; at Briançon (France), 1321 metres above sea level, 643 m.m. barometer, at 95.4°, as by the action of the so-called Norwegian cooking apparatus.

Les Mondes, December 7, 1871.

Mineral Riches of Japan.—M. Sévoz.—In the shape of a letter addressed to the excellent editor of this periodical, the author communicates some interesting facts on the metallurgical industry of the country just named, wherein coals are found, and gold and silver, copper, lead, and iron are extracted from their ores or from the rocks wherein they are imbedded. The Japanese work iron by an imperfect method called the Catalan method. After smelting, the slag still contains 40 per cent of metallic iron; a small blast-furnace will, however, be built by the author at the locality where this iron ore is found. The natives are excellent miners, but were until lately unacquainted with the use of gunpowder in mining operations.

Experiments made by Thermo-Dynamics.—F. Tommassi.—For the purpose of proving the possibility of converting into dynamical work the dilatation produced in liquids by heat; the facility to utilise this motive force for the purpose of working hydraulic presses. Illustrated by a series of woodcuts.

La Revue des Scientifique de la France et de l'Etranger,
November 4, 1871.

This number does not contain any original papers relating to chemistry.

December 2, 1871.

Although the titles of the following original papers do not strictly belong to the subject-matter usually treated in our columns, we call attention to them for their general scientific interest:—

International Congress of Anthropology and Pre-Historic Archaeology; Meeting at Bologna, Italy.—A highly valuable record of well observed and digested facts.

Origin of the Sedimentary Terrains (Rocks, Coal, &c.).—Ch. Contrejeau.—A very clear exposé of geological facts.

December 9, 1871.

In this number we meet with the—

Compte Rendu of the Daily Meetings of the Last Session (September) of the International Congress of Anthropology and Pre-Historic Archaeology at Bologna.—M. Cazalis de Fondouce.

Present State of Aërial Navigation and the Attempts made to Steer Air-Balloons.—W. de Fonvielle.

Polytechnisches Journal von Dingler, first number for November, 1871.

Continuation and End of Essay on Blast-Furnaces for Making Pig-Iron.—C. Schinz.

Contribution to the History of the Recovery of Sulphur from Alkali Waste.—L. Mond.—The real gist of this paper turns upon a question of priority of invention. It appears that the author has been very unjustly accused in papers published abroad of perverting and patenting inventions not his own, but the property and invention of others. The author, in this paper, proves not only that there is not the remotest ground for such base assertions, but that he was the first who devised a practicable and advantageous method for extracting sulphur from alkali waste on the large scale now some twelve years ago.

Water contained in some of the Double Sulphates.—H. Rheineck.—Protosulphate of iron and ammonia, $\text{NH}_4\text{FeS}_2\text{O}_8 + 5\text{H}_2\text{O}$ —equivalent, 187.4; water, 24.72 per cent. Protosulphate of iron and potassa, $\text{KFeS}_2\text{O}_8 + 5\text{H}_2\text{O}$ —equivalent, 203; water, 21.63 per cent. Ammonio-sulphate of magnesia, $\text{MgNH}_4\text{S}_2\text{O}_8 + 6\text{H}_2\text{O}$ —water, 33.33 per cent. Ammonio-sulphate of copper, $\text{CuNH}_4\text{S}_2\text{O}_8 + 6\text{H}_2\text{O}$ —water, 27.04 per cent. and CuSO_4 , 39.56 per cent. The author has analysed these salts volumetrically, care being taken to obtain the substances in a pure and perfectly crystalline state.

Suggestion for the Means of Preventing as much as possible Explosions occurring with Detonating and Explosive Substances, more especially Fulminate of Mercury, when prepared for the purpose of Filling Percussion Caps.—Dr. Ph. Neumann.—This paper bears entirely upon the making of percussion caps. The author proves, by a series of facts elucidated by experiments, that the operations of granulation and mixing of the fulminate are best and most safely conducted in vacuum.

Phenomena of Fermentation.—H. Rheineck.—However valuable in a scientific sense, the contents of this paper are not well suited for any useful abstraction.

Brewing Industry of the Austro-Hungarian Empire.—G. Yoback.—A lengthy statistical essay on the beer production of the country alluded to.

NOTES AND QUERIES.

Comparative Tables of Hydrometers.—(Reply to L. C.).—You will find the latest comparative tables of hydrometers in *Zeitschrift für Analytische Chemie*, von R. Fresenius, 1870, p. 437.—V. C.

Comparative Tables of Hydrometers.—(Reply to L. C.).—You will very likely find what you desire in "Sammlung Physikalischer Tabellen," von Dr. E. L. Schubarth; Berlin, 1849 or later, 8vo., 200 pages.

Naphthalic Acid.—(Reply to "Naphthaline").—By prolonged boiling of naphthaline with nitric acid, the former body is converted into a mixture of oxalic and naphthalic acids. Consult, further, Miller's "Elements of Organic Chemistry," part iii., p. 707, 4th edition.

Apparatus for the Liquefaction of Gases.—(Reply to S. T.).—Consult Müller-Pouillet's "Lehrbuch der Physik," Gehlert's "Physikalisches Lexikon," or Precht's "Technologische Encyclopedie," all of which books you may inspect at the Patent Office Library.

Gas-Proof Fabric.—(Reply to "L.R.C.P. Ed.").—The Nylonte Company (Limited), 7, Great Winchester Street Buildings, London, E.C., are supplying hospitals, &c., with a cheap kind of collodion, which is also made into the finest of tissues both with and without a fibrous material; in some respects it is superior to either gutta-percha or india-rubber.—S. E. P.

Adulterations in Food and Drink.—In answer to "An Amateur Chemist," I would repeat that hackneyed saying "there is no royal road to chemistry," and especially to the detection of adulterations in food and drink. Very few illicit admixtures are capable of detection by chemical means; the majority require considerable acquaintance with the microscope, and many are determined by mechanical means—i.e., such as density, &c. Hassall's book is one of the best, and "An Amateur Chemist" will find no shorter way to the subject than by a careful perusal of such a one.—S. W. MOORE.

Heat and Electricity.—No doubt Mr. Wilson is right as to what ought to be done for a full determination of the laws of this subject. I hope soon to have time to carry out experiments more fully; meanwhile I only wished to call the attention of experimentalists to the matter. Till it is more fully investigated it is scarcely worth while to say anything more about it. But, perhaps, I may add that I found, quite contrary to what might be expected, that a zinc and sulphate of copper battery giving a current of 75° on the tangent galvanometer would keep hot three or four times the length of wire which a zinc and platinum element would, though, from the electro-motive power of the elements respectively, one would have expected just the contrary result. However, after a short time I hope to experiment fully and ascertain whether the laws derived from elements of the same kind apply to elements of different kinds.—H. HIGHTON.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 18th.—London Institution, 4. Prof. Huxley, LL.D.
F.R.S., on "Elementary Physiology."

— Medical, 8.
— Anthropological, 8.

TUESDAY, 19th.—Civil Engineers, 8.

WEDNESDAY, 20th.—Society of Arts, 8.

— Geological, 8.

THURSDAY, 21st.—Royal, 8.30.

— Zoological, 4.

— Chemical, 8. Mr. H. Bassett, "On Eulyte and Dyslyte."

— Philosophical Club, 6.

FRIDAY, 22nd.—Quekett Microscopical Club, 8.

TO CORRESPONDENTS.

F.R.C.S.—(1). You will find all the information you require in Brande's "Manual of Chemistry," 6th edition, vol. i., pp. 457 to 464. (2). There are several kinds of apparatus in use for condensing carbonic acid gas; Natterer's is readily worked.

L. Mond.—Your communication has received attention.
C. T. Kingzett, C. Crump, F. Cruise, W. Valentin, and J. Parry, are thanked for their communications.

Now ready, price 4s., with Coloured Frontispiece of the more important of the Spectra,

INORGANIC CHEMISTRY,

By the late PROFESSOR GEORGE WILSON, of Edinburgh University.

Thoroughly revised and brought up to the latest state of the Science by H. G. MADAN, M.A., Fellow of Queen's College, Oxford, and Natural Science Master in Eton College.

W. and R. Chambers, London and Edinburgh.

TEXT-BOOKS OF SCIENCE.

On Tuesday, December 19th, in small 8vo., price 3s. 6d.,

The Theory of Heat. B. J. Clerk Maxwell, M.A., F.R.S.S. L. & E., Professor of Experimental Physics in the University of Cambridge.

Being the Sixth of the New Series of Elementary Works on Mechanical and Physical Science in course of publication, edited by Professor T. M. GOODVE, M.A.

Text-Books previously published, price 3s. 6d. each:—

1. GOODEVE'S MECHANISM.
2. BLOXAM'S METALS.
3. MILLER'S INORGANIC CHEMISTRY.
4. GRIFFIN'S ALGEBRA AND TRIGONOMETRY.
5. WATSON'S PLANE AND SOLID GEOMETRY.

London: Longmans, Green, and Co., Paternoster Row.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prossiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND Co., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE OF CHEMISTRY.—

EXPERIMENTAL MILITARY AND NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c.: of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Methylated Spirits.—David Smith Kidd,

Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Silicates of Soda and Potash in the state of

Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C. who hold stock ready for delivery.

ANALYTICAL LABORATORY AND SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied and the erection of Plant and Buildings is superintended when required.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA of HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2½d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar Sold by all Italian Warehousemen, Grocers, Chemists, and Ships. Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT of MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British French, Prussian, Russian, and other Governments.

ESTABLISHED 1798.

ROBERT DAGLISH & CO., BOILER MAKERS, ENGINEERS, AND MILL-WRIGHTS, BRASS AND IRONFOUNDERS, ST. HELEN'S FOUNDRY, LANCASHIRE.

Makers of every description of Chemical, Colliery, Copper Ore Mining, and Glass Machinery, including Crown, German Sheet, and Plate Glass Plant, as supplied to some of the largest Firms in England, Ireland, Scotland, and Wales.

Makers of the latest Improved Revolving Black Ash Furnace, with Siemens's Patent Gas Arrangement, and as used in the Manufacture of Soda.

Improved Vertical Blowing Engines (which have given a much higher Blast than any others have yet obtained), and as supplied to the entire satisfaction of most of the largest Bleaching Powder Manufacturers who have adopted "Weldon's Patent Process."

Authorised by Patentee to supply the Ironwork and Plant required in the Manufacture of Bleaching Powder by "Deacon's Patent."

Plans and Estimates of the Plant required for working these Patents in accordance with the Patentee's instructions.

Photographs, Prices, and other information, supplied on receipt of Order.

PHOTOGRAPHIC AND OPTICAL WAREHOUSE.

J. SOLOMON,

22, RED LION SQUARE, LONDON, W.C.,

PATENTEE OF MAGNESIUM LAMP FOR ENLARGING PHOTOGRAPHS.

Photographs vitrified on Enamel or Porcelain for the trade

Catalogues on Application.

THE CHEMICAL NEWS.

VOL. XXIV. No. 630.

NOTES ON FLUORESCENCE.

By HENRY MORTON, Ph.D.

(CORRECTION).

THROUGH a series of accidents, I was prevented from obtaining access to Professor Stokes's papers on fluorescence in the *Philosophical Transactions* until the present time. I thus failed to be aware that two observations casually mentioned in my previous "Notes" or "Observations" on this subject had been previously made and discussed by this eminent physicist.

The points to which I allude are the effect of hydrochloric acid on quinine sulphate and the increase of fluorescence in solutions of the latter substance by dilution.

ON FLUORIDE OF SILVER.*

By G. GORE, F.R.S.

PART III.

In this communication the author has finally shown that the action of iodine, under the influence of heat (including the process described by Kammerer, *Phil. Mag.*, 1863, vol. xxv., p. 213, for the isolation of fluorine), does not liberate uncombined fluorine, but produces fluoride of iodine and iodide of silver, a double salt, composed of iodide of silver and fluoride of platinum, being produced at the same time by corrosion of the platinum vessels, if the temperature approaches a red heat.

The fluoride of iodine produced is a highly volatile and colourless liquid, does not corrode mercury or red-hot platinum, corrodes glass at 60° F., and crystals of silicon at a red heat, also platinum in contact with argentic fluoride in a state of fusion; it instantly turns a deal splint black, fumes powerfully in the air, and is decomposed with violence by water into hydrofluoric and iodic acids, in accordance with the following equation,

It dissolves iodine, and is absorbed by that substance; it is also absorbed either by argentic fluoride or iodide when those substances are cooled in its vapour, and may be expelled from them at a red heat. Its vapour quickly darkens the colour of a deal splint, and very gradually turns paraffine brown.

The platinum vessels in which the reaction with iodine was effected were considerably corroded (but less so than when bromine or chlorine were employed), and many expensive vessels were rendered useless by this cause during the experiments.

No chemical change occurred on heating argentic fluoride to redness with pure carbon.

By heating this fluoride to redness in a current of dried coal-gas, it was wholly reduced to metallic silver, hydrofluoric acid and tetrafluoride of carbon being evolved.

In liquid cyanogen, argentic fluoride neither dissolved nor suffered chemical change, but at a low red heat, in a current of dry cyanogen gas, it was entirely reduced to metal, either nitrogen and tetrafluoride of carbon, or fluoride of cyanogen being liberated. An aqueous solution of silver fluoride was precipitated by passing a prolonged current of cyanogen gas through it. Fluoride of silver was also decomposed by fusion with paracyanogen.

Argentic fluoride was not dissolved or chemically changed by immersion in anhydrous liquefied hydrocyanic

acid, but by passing the dry acid in vapour over the red-hot salt, the latter was decomposed and metallic silver liberated. Aqueous hydrocyanic acid readily precipitated a solution of argentic fluoride.

Fluoride of silver was not decomposed by heating it to redness in an atmosphere of carbonic oxide or carbonic acid gases.

By fusing the fluoride in a current of vaporous tetrachloride of carbon, it was wholly converted into argentic chloride, the vessels being much corroded, and an insoluble double salt of platinum and silver formed. Similar results took place on using tetrachloride of carbon. Silver fluoride was insoluble, and remained unchanged in liquid tetrachloride of carbon at 60° F.; and tetrachloride or tetrachloride of carbon had no chemical effect upon an aqueous solution of the silver-salt. A solution of bromine or indine in tetrachloride of carbon was quickly decolourised by agitation with small particles of argentic fluoride.

Crystals of boron did not decompose fluoride of silver at a low red heat, nor chemically change at 60° F., an aqueous solution of the salt containing either free hydrofluoric or nitric acids.

Vitrified boracic acid violently decomposed fluoride of silver in a state of fusion, emitting copious white acid fumes, but it had no chemical effect upon an aqueous solution of the salt at 60° F.

By placing crystals of silicon upon argentic fluoride in a state of fusion, they become at once red-hot, undergoing rapid combustion, and evolving fluoride of silicon. A lump of fused silicon slowly decomposed an aqueous solution of fluoride of silver, setting free metallic silver in crystals. Crystals of silver behaved similarly, but much more rapidly, and evolved abundance of gas if the solution contained free hydrofluoric acid; on adding nitric acid to this mixture, bubbles of spontaneously inflammable silicide of hydrogen gas were evolved and ignited.

Pure and dry precipitated silica added to fluoride of silver, at a temperature of low redness, evolved much heat, with violent action, and set free metallic silver.

No chemical change took place on passing fluoride of silicon over red-hot fluoride of silver.

Argentic fluoride in a state of fusion is rapidly decomposed by sulphur with evolution of heat; fluoride of sulphur is at the same time produced, and argentic sulphide formed. To ascertain whether fluoride of sulphur is a gas or a volatile liquid, an apparatus called a "gas collector" was devised and employed, and a full description of its construction is given. By using this apparatus, substances may be heated without contact with the external air, and without subjecting the joints of the apparatus in which they are heated to leakage by expansion or contraction of the gaseous contents.

Fluoride of sulphur was found to be a heavy colourless vapour, uncondensable at the temperature of melting ice and at the ordinary atmospheric pressure. It corrodes glass, fumes strongly in the air, and has a characteristic and very powerful dusty odour, not very unlike that of a mixture of chloride of sulphur and sulphurous anhydride. Sulphur rapidly decomposed an aqueous solution of argentic fluoride.

Sulphurous anhydride passed over fluoride of silver at an incipient red heat, produced little or no decomposition of the silver-salt. Vaporous fluoride of sulphur also produced no visible effect.

By passing the vapour of liquid chloride of sulphur over the fluoride in a state of fusion, chemical action occurred, a vapour was evolved which corroded glass, and possessed a dusty odour, but did not condense to a liquid; it was probably fluoride of sulphur. The saline residue consisted of argentic chloride and sulphide. A solution of argentic fluoride was decomposed by agitation with liquid chloride of sulphur, hydrofluoric acid being evolved, and argentic chloride and sulphide produced.

Argentic fluoride did not dissolve in bisulphide of carbon. By passing the vapour of the latter substance over the silver-salt at a red heat, a chemical change took

* Abstract of a Paper read before the Royal Society.

place, and a fuming acid vapour was evolved, in accordance with the following equation:— $4\text{AgF} + \text{CS}_2 = \text{Ag}_2\text{S} + \text{CF}_4$. A solution of bromine or iodine in bisulphide of carbon was rapidly decolourised by agitation with particles of argentic fluoride, and the liquid acquired the odour of tetrafluoride of carbon.

NOTES OF

DEMONSTRATIONS ON PHYSIOLOGICAL
CHEMISTRY AT ST. GEORGE'S HOSPITAL.

By S. W. MOORE.

VII.

Blood, seen by the unaided eye, is a red fluid; when observed through a microscope of tolerably good magnifying power, appears to consist of a yellow fluid, in which may be seen floating corpuscles; these are red and white. In human blood the red corpuscle is about $\frac{1}{34000}$ of an inch in diameter, the white about three times this size, and in proportion of 2 or 3 white to 1000 red.

The constituents of blood are albumin, fibrin (?), hematin, and globulin; oleic, stearic, lactic, phosphoric, sulphuric, and hydrochloric acids, in combination with Na, K, Ca, Mg, &c.; cholesterine and phosphorised fat. The blood is so intimately connected with every change going on in the system that its composition is not the same at any two periods; the constant changes also generate heat, the degree of which may be estimated with a thermometer either at the mouth or rectum, the latter giving the better results.

Blood under certain conditions coagulates, becomes solid; the clot formed contracts, and serum separates, forming the condition known to the ancients as the "buffy coat;" this phenomenon is due to the formation of a substance called fibrin. There are several speculative theories regarding this body: the one most credited at present being that it is formed from two different elements uniting, a "fibrinoplastic" and fibrinogenous; one existing in the corpuscles, the other in the serum.

Fibrin, which has the same composition as albumin, is considered by some to be a waste product: this is very doubtful; the subject, however, is too lengthy for discussion here.

Fresh fibrin decomposes H_2O_2 with evolution of O.

Freshly drawn blood, when whipt with twigs or shaken up in a bottle with fragments of zinc, yields fibrin in a coagulated form. This coagulation may be accelerated by a temperature of more than 50°C ., the electrical current, contact with air, and agitation; it may be retarded by cold, contact with living membranes, diluting with water, or mixing with such salts as Na_2SO_4 , NaCl , the alkaline carbonates, and KNO_3 . Fresh blood freezes at 0°C ., and can be melted without perceptible change.

During respiration, the blood undergoes very important changes, the appreciable alteration being in the corpuscles, due evidently to the oxidation of their hematin.

On entering the lungs, the blood is exposed to a vast surface of air by its distribution in the capillaries; O is absorbed, and the blood assumes a bright-red colour, losing CO_2 . The exhalation of CO_2 from the lungs occurs to so great an extent that it is calculated that about 8 ozs. of C are given off in twenty-four hours: we may thus look on the corpuscles as carriers of O to the various tissues for the purpose of the interchange necessary to burn up effete matters. These changes may be observed to perfection by the aid of the spectroscope.

Many gases may be respired without ill effect; others, such as CO_2 and N, cause death from the absence of O, whilst others, as H_2S , AsH_3 , PH_3 , HCN , CO, &c., are poisons of a very active nature.

There are several gases contained in the blood; these may be separated by the aid of the air-pump.

EXAMPLES FOR PRACTICE IN QUANTITATIVE
ANALYSIS.

By ALEXIS A. JULIEN,

Assistant in Charge of the Quantitative Laboratory of the School of
Mines, Columbia College.

(Concluded from p. 9).

EXAMPLE No. 9.—*Determination of the Alkalies in Silicates.*

Pulverise very finely, weigh out 2 grammes, mix with 2 grms. of dry NH_4Cl , add 16 grms. of CaCO_3 , mix intimately, transfer completely to a platinum crucible, warm gradually until fumes of ammonia salts no longer appear, and heat to full redness, but not too intensely, for 30 to 40 minutes. Cool, boil with 100 c.c. of H_2O until no lumps remain, filter, and wash thoroughly. To the filtrate add $(\text{NH}_4)_2\text{CO}_3$ in slight excess, concentrate to about 30 c.c., add a little more $(\text{NH}_4)_2\text{CO}_3$, and some $(\text{NH}_4)_2\text{O}$, filter and wash. Evaporate the filtrate in a weighed dish on the water-bath to dryness, then heat in an air-bath, and finally heat carefully almost to redness, to expel ammonia salts, cool, and weigh. Result, $\text{NaCl} + \text{KCl}$. If, on re-dissolving in a little water, an insoluble residue appears, separate and determine it on a very small filter.

To the solution of the alkaline chlorides add an excess of a concentrated neutral solution of PtCl_4 , evaporate nearly to dryness on a water-bath below the boiling-point, treat the residue with alcohol (sp. gr. $0.86-0.87$), cover, and allow to stand a few hours with occasional stirring, and decant upon a small filter. If the fluid is of a deep yellow colour, and no white saline particles are to be seen mixed with the yellow crystalline precipitate, a sufficient quantity of the precipitant has been added. Transfer to the filter, wash thoroughly with alcohol, dry, wrap up the filter, place in a small weighed porcelain crucible, cover, heat until the paper is completely charred, remove the cover, burn off the carbon, cool, throw in a very minute portion of pure oxalic acid, cover, and ignite, gently at first, finally to a strong red-heat, and cool. Treat with water, and wash the residuary platinum by decantation, until the last rinsings remain clear upon addition of argentic nitrate. Dry, ignite, and weigh. One equivalent of platinum represents one equivalent of potassium; and the amount of KCl is thus readily calculated.

EXAMPLE No. 10.—*Analysis of Iron Ores.*

General Scheme.—Prepare an average sample for analysis (Note 1). Make a qualitative examination for Cr_2O_3 , Cu, As, and Ti.

The ore generally contains Ca, Mg, Al, Fe, Mn, S, P, H_2O , SiO_2 , and may contain Na_2O , K_2O , Cr_2O_3 , Zn, Ni, Co, Cu, As, SO_3 , TiO_2 , V_2O_5 , WO_3 , CO_2 , Cl, F, organic matter.

I. Special Determinations.—A. In 1 grm. determine H_2O by direct weight. B. In 1 grm. determine CO_2 by direct weight, as in example 7. C. For special determinations of K_2O , Na_2O , Cr_2O_3 , FeO , As, S, SO_3 , TiO_2 , V_2O_5 , WO_3 , Cl, F, organic matter, see Appendix.

II. Main Analysis.—Pulverise 5 grammes to impalpable powder, and fuse thoroughly in platinum crucible (Note 2) with 20 grms. Na_2CO_3 (increasing to 30 grms. as the ore contains more SiO_2 and silicates) and 2 grms. NaNO_3 (increasing to 5 grms. as the ore contains more FeO, sulphides, or organic matter). After cooling, treat crucible and fused mass in a small beaker with boiling water, until the mass is thoroughly disintegrated (Note 3). If the solution has a decided green colour, digest with a little alcohol, filter, and wash with hot water (Note 4).

1. Water Solution.—It must be perfectly clear, but may be coloured. It may contain Al_2O_3 , ZnO , SiO_2 , SO_3 , P_2O_5 , CrO_3 , As_2O_5 .

Add excess of HCl, evaporate to dryness (Note 5), moisten residue thoroughly with HCl, digest with hot water, filter, and wash with hot water.

NOTE 1. *Sampling the Ore.*—Break up in an iron mortar 40 or 50 lbs. into pieces that will pass through a tin sieve with $\frac{1}{4}$ -inch holes. Thoroughly mix the fine and coarse. Break up about 10 lbs. of average quality, so that it will pass through a tin sieve with $\frac{1}{4}$ -inch holes. Mix well, take 1 lb., and pulverise in iron mortar until it will pass through brass sieve of 60 meshes to the linear inch. Mix well, take out about 30 grammes, pulverise in iron mortar, pass through muslin bolting-cloth, and put into a small bottle, tightly corked, for analysis and special determinations. It is yet necessary that every portion of this, required for the main analysis or a special determination, should be further pulverised, as needed, in the agate mortar, to an *impalpable powder*.

NOTE 2. *Preliminary Fusion.*—Thoroughly mix the ore and its fluxes on glazed paper, put about a third of the mixture in a 2-oz. platinum crucible, the lower portion of whose interior surface has been previously lined with a thin layer of Na_2CO_3 , and heat over a common Bunsen burner, with a strong flame, until the greatest violence of the effervescence has ceased. Then add and treat the two-thirds remaining successively, and with the same precaution. Finally, heat strongly over the blast-lamp until the mass is in complete and quiet fusion, adding a little more Na_2CO_3 , should it not readily fuse.

NOTE 3. *Removal of the Fused Mass.*—Let the crucible cool until just below red-heat, and place it on a clean and dry iron plate, whose lower part is immersed in cold water. When the crucible is cool enough to hold in the hand, put it into the smallest beaker in which it can lie upon its side, and digest with boiling water. The fused

mass will generally soon become detached from the crucible, and come out in a cake. Then remove the crucible, wash it, treat in a small beaker with a little conc. HCl , to remove any adhering particles of the mass, and add this solution to that of the Insoluble Residue (2). Should any portion of the fused mass, thicker than a film, obstinately resist solution in the hot water, it must be removed only by patience and long boiling; and no attempt should be made either to *dig* it out or to dissolve it in HCl , lest by the formation of aqua regia or free Cl (in presence of the NaNO_3 or Mn_2O_3) the crucible may be attacked and injured.

NOTE 4. *Reduction of H_2MnO_4 .*—If alcohol is added to the solution, heat on the water-bath, to avoid any risk of breaking the beaker by the bumping of the residue in the boiling solution. If there was no bluish-green tint in the fused mass, nor decided green colour in its solution, it is unnecessary to add alcohol.

NOTE 5. *Separation of SiO_2 .*—In order to render the SiO_2 entirely insoluble, the evaporation should be carried to perfect dryness, until no odours of HCl can any longer be detected, and the mass is hard and crumbly. As the residue is to be re-fused with Residue (b), the drying may be completed at a temperature somewhat higher than 100°C .

NOTE 6. *Removal of As.*—The As has already been mostly or completely volatilised in the foregoing evaporation. If a trace is still suspected to remain, either repeat the evaporation with HCl or else employ the following method:—Saturate with H_2S gas, filter, wash, add a little KClO_2 to the filtrate, and boil until the S is completely oxidised.

NOTE 7. *Determination of Cr_2O_3 .*—In order to oxidise all the Cr_2O_3 in the solution, either of the following methods may be employed:—

(j). Add Na_2CO_3 almost to neutralisation, and then sodic acetate in excess. Pass Cl or add Br. to saturation. Boil gently, keeping solution almost neutral by occasional additions of Na_2CO_3 , until all excess of Cl or Br is expelled.

(k). Add pure KHO in excess, and boil with sufficient Br. Cool, add HNO_3 almost to neutralisation, acidulate with acetic acid, add sodic acetate in excess, and boil.

Filter out hot the basic aluminic acetate precipitated as above, and wash with hot H_2O containing a little sodic acetate. To filtrate add baric acetate in slight excess, filter, and wash. This last filtrate and the precipitate of aluminic acetate contain all the P_2O_5 and Al_2O_3 in the Water Solution. The latter is to be dissolved in HCl , the former to be freed from the excess of baric acetate with dilute H_2SO_4 , and both to be added to Solution (d¹).

Digest the precipitate of BaCrO_4 and BaSO_4 with conc. H_2SO_4 , boil, filter, and wash. Then adopt either of the following methods:—

(l). Boil the filtrate with conc. HCl and alcohol, to reduce CrH_2O_4 to Cr_2O_3 , and precipitate the latter with $(\text{NH}_4)_2\text{O}$.

(m). Add $(\text{NH}_4)_2\text{O}$ in excess, pass H_2S gas until saturation, keeping the liquid near the boiling-point. When Cr_2O_3 is completely precipitated, filter, wash thoroughly with hot water, dry, &c.

NOTE 8. *Precipitation of BaSO_4 .*—Avoid the addition of a large excess of BaCl_2 solution. Add only 5 c.c. at first, and then, after complete subsidence of precipitate, add a few drops to determine if any H_2SO_4 remains unprecipitated, &c. Then proceed as in Example No. 2, B.

NOTE 9. *Separation of SiO_2 .*—Evaporate as in Note 5. Then add HCl pretty freely, and warm for some time before adding any water, as the high heat may have produced anhydrous Fe_2O_3 , forming an oxychloride which is very slow to dissolve, especially in dilute acid. Should the acid already added be too dilute, concentrate by evaporation, add conc. HCl , and digest at a moderate heat.

NOTE 10. *Determination of TiO_2 .*—After weighing the precipitate, ignite it strongly in H gas to reduce the Fe_2O_3 , cool, dissolve out all the metallic Fe by boiling with dilute H_2SO_4 , filter, wash, dry, ignite, and weigh in platinum crucible ($\text{TiO}_2 + \text{Al}_2\text{O}_3$). In the filtrate determine the Fe volumetrically (Note 18). Fuse the residue with about six parts of KHSO_4 , in which it will readily dissolve. Cool, take up the fused cake in cold water, filter if necessary, add one or two drops of dilute HNO_3 , and precipitate the TiO_2 in the very dilute solution by long boiling (usually six to eight hours). Filter, wash with acidulated water, dry, and ignite. Should the ignited TiO_2 be coloured by FeO_2 , repeat the process. When there is much TiO_2 in the ore, a special determination should be made (see Appendix); or the percentage found as above should be added to that of the part found in (c⁷) by treating that precipitate in exactly the same way.

NOTE 11. *Precipitation of the Basic Acetates.*—Dilute the solution to about 1 litre for each gramme of the sesquioxides present. It is sufficient to boil from 10 to 15 minutes for the complete precipitation of the acetates. The filtering should be done rapidly on a ribbed filter, keeping the fluid hot, and disturbing the settled precipitate as little as possible. After the supernatant fluid has been poured through the filter, throw on the precipitate, and wash it with boiling water containing a little sodic acetate. Should any basic acetate separate upon concentrating the filtrate, add some sodic acetate, boil, filter, dissolve the precipitate in HCl , and unite to the solution of the main body.

NOTE 12. *Determination of P_2O_5 .*—The removal of HCl may be effected by evaporating the solution with a large excess of HNO_3 , until a glass rod, moistened with AgNO_3 and held over the surface of the liquid, is no longer clouded by the escaping vapours. Or still better,

in some hands, add $(\text{NH}_4)_2\text{O}$ suddenly in large excess, filter, wash once, and re-dissolve in boiling HNO_3 .

NOTE 13. *Determination of Al_2O_3 .*—It is generally more accurate to determine the Al_2O_3 directly in this precipitate, as follows:—Dissolve by long boiling in a flask with conc. HCl , remove from the flame, reduce the Fe_2O_3 by Na_2SO_3 . Boil some time, neutralise with Na_2CO_3 , add solution of pure KHO or NaHO in excess, boil some time, allow to settle, decant the clear liquid through a filter, boil again with KHO, decant, and wash, first by decantation, afterwards on the filter with hot water. Acidify the filtrate with HCl , boil with a little KClO_3 , concentrate, and precipitate the Al_2O_3 (+ TiO_2 , if present) with $(\text{NH}_4)_2\text{O}$. Other methods are given by A. Frönde. (*Zeits. für An. Chem.*, 1866, 395).

NOTE 14. *Precipitation of the Sulphides.*—Add no more of the yellow sulphide of ammonium than is required, as an excess will re-dissolve a portion of the precipitate unless much NH_4Cl be present. But an excess of the latter reagent will interfere with the concentration necessary to precipitate the MgO in Filtrate (h). Cork the flask tightly before setting it aside.

NOTE 15. *Separation of Co and Ni.*—Should these constituents be present in considerable quantity, which very rarely happens, it is better, as the nickelic sulphate is likely to be partially converted into NiO strong ignition, to dissolve the sulphides in aqua regia, neutralise with KHO, precipitate and determine the CoO by Genth and Gibbs's process, and in the filtrate determine the Ni as oxide.

NOTE 16. *Determination of Mn.*—(Gibbs's process. *Am. Journ. Sci.*, xlv., p. 216). To the HCl solution, free from H_2S , add $(\text{NH}_4)_2\text{O}$ in excess, and solution of Na_2HPO_4 in large excess. Then add dilute H_2SO_4 or HCl until the white precipitate re-dissolves, heat to boiling, and add $(\text{NH}_4)_2\text{O}$ in excess. Digest near the boiling-point about an hour, when the precipitate, at first white and gelatinous, becomes crystalline in rose-coloured scales. Filter, and wash with hot water. If tinged red, re-dissolve the precipitate in dilute HCl , and repeat the process. On ignition the precipitate is converted into $\text{Mn}_2\text{P}_2\text{O}_7$, a nearly white powder. If Zn is present, it must first be separated as ZnS , as in the scheme.

NOTE 17. *Precipitation of Dissolved NiS.*—A trace of NiS, which is somewhat soluble in sulphide of ammonium, is often carried through into this filtrate, but is completely thrown down, along with the excess of S, by this acidulation.

NOTE 18. *Volumetric Determination of Fe.*—Put Solution (d²) directly into a flask holding 200 c.c., cool, dilute with cold water exactly up to the mark, mix by pouring back and forth several times from the flask to a beaker, draw out 100 c.c. with a pipette known to deliver that quantity, empty it into one reduction bottle, and into another empty the flask, and rinse out the flask, beaker, and pipette. The reduction bottle consists of a wide-mouthed bottle, holding about 250 c.c., with its lip ground down perfectly smooth, and covered by a ground-glass plate loosely held to its place by wires. Carefully let down in each bottle a lump of amalgamated zinc, free from Fe, and a strip of platinum foil resting upon it, add about 10 c.c. of conc. H_2SO_4 , cover, and set aside overnight. When the reduction is complete the solution will be colourless.

Then in each of two flasks, holding about 75 c.c., introduce exactly 0.2 gramme of fine iron wire, add an excess of dilute H_2SO_4 , and immediately adjust corks (having bent tubes attached, with their ends immersed in small beakers of warm water), and heat until the complete solution of the wire. By this water-valve arrangement the entrance of air and oxidation of the FeSO_4 solution are avoided, and when the water begins to run back, after the evolution of H has ceased, its warmth prevents the too sudden reduction of the temperature, and condensation of the vapours in the flasks. After cooling, pour and wash out the contents of each flask, with the beaker of

water attached, into a large beaker, add dilute H_2SO_4 in excess, dilute to about 1 litre, and titrate successively and rapidly with the solution of KMnO_4 , to determine its strength.

Now pour and wash the contents of each reduction bottle into a large beaker, add dilute H_2SO_4 , dilute to about 1 litre, and titrate successively as before. In a HCl solution all possible excess of that acid must be avoided, and the solution must be diluted to about 2 litres. When greater accuracy is desired the HCl may be replaced, previously to the reduction, by evaporating the solution with excess of H_2SO_4 .

When the ore contains TiO_2 the process given in Note 10 must precede this determination, because any TiO_2 present in the solutions put in the reduction bottles would be reduced (yielding a pink tinge), as well as the Fe_2O_3 , and consume a portion of the KMnO_4 in its re-oxidation.

Another method has been recently published (*American Chemist*, July, 1870, p. 23), by which the previous reduction of the iron is not required, and a solution of CuCl_2 is employed for titration, but its accuracy has not yet been confirmed.

APPENDIX.—SPECIAL DETERMINATIONS.

Alkalies.—Weigh out 5 grms., and determine as in Example No. 9.

Chromium.—Fuse, &c., as in Main Analysis, obtain Filtrate (a) of the Water Solution, and determine the Cr as in Note 7. But if the ore be chromic iron, either of the four following methods may be employed for its decomposition, after it has been pulverised to an impalpable powder. Little is known in regard to their comparative accuracy and convenience, especially of the last two.

(a). **Hunt's Method.**—Mix 0.5 grm. of ore with 6 grms. KHSO_4 in a large platinum crucible, fuse for 15 minutes at a temperature scarcely above the fusing-point of the salt, and then raise the heat somewhat, so that the bottom of the crucible may just appear red, and keep it so for 15 to 20 minutes. The fusing mass should not rise higher than half-way up the crucible. Then heat until the fumes of H_2SO_4 no longer escape. Now add 3 grms. Na_2CO_3 , heat to fusion for an hour at a gentle red-heat, adding 3 grms. KNO_3 in small portions from time to time, and then heat for 15 minutes to bright redness, and cool. Treat with boiling water, filter hot, wash with hot water, digest the residue with HCl , and, if anything then remains undissolved, subject it again to the above operation. To the alkaline filtrate add an excess of $(\text{NH}_4)_2\text{NO}_3$ in excess, evaporate on a water-bath nearly to dryness, and until all free ammonia is expelled, filter, and wash. The CrO_3 is determined in this solution.

(b). **Gibbs's Method** (*Am. Journ. Sci.*, II., xxxix., p. 59).—Fuse over blast-lamp with 10 to 15 parts KF , HF , digest with H_2SO_4 until F is expelled, add hot water, and filter.

(c). **Britton's Method** (*Journ. Frank. Inst.*, March, 1870).—Weigh 0.5 grm., mix with 4 grms. of the flux (1 part $\text{KCl}_3\text{O} + 3$ parts soda-lime), ignite in a platinum crucible at a bright red-heat for over $\frac{1}{2}$ hours, cool, triturate the sintered mass in a porcelain mortar, digest in a 4 oz. beaker with 18 c.c. of hot water, boil for 2 or 3 minutes, cool, add 15 c.c. of HCl , and stir for a few minutes until solution. Pour into a known quantity of solution of FeSO_4 , and determine volumetrically the amount of iron which remains unoxidised by the CrO_3 .

(d). **Pearson's Method** (*Am. Journ. Sci.*, Sept., 1870).—Place 0.5 grm. of ore in an evaporating dish, add sufficient conc. HNO_3 to cover it, add a little KClO_3 , cover with an inverted funnel, and digest, adding small quantities of KClO_3 from time to time, until the ore is thoroughly decomposed. Dilute, filter, and wash. Dry the residue, fuse it with a mixture of Na_2CO_3 and KNO_3 , cool, dissolve in hot water, and test the solution for Cr. If none

is found, the entire amount will be found in the above filtrate.

Ferrous Oxide.—Digest 1 grm. of ore, finely pulverised, in a flask with conc. HCl , passing a current of carbonic anhydride. After complete decomposition, cool in carbonic anhydride, and immediately titrate the solution of FeCl_2 , without removing the insoluble residue, with KMnO_4 (Note 18). The presence of organic matter and of the higher oxides of Mn will interfere with the accuracy of the process.

For a special determination of the entire amount of Fe in an ore, either this method may be employed, omitting the use of carbonic anhydride, and reducing by Zn, as in Note 18; or the ore may be decomposed by fusion, as in the Main Analysis, without the use of Na_2NO_3 ; or, in the case of chromic iron, either of the above-mentioned four methods may be used; or Clarke's method may be employed, as follows (*Am. Journ. Sci.*, xlv., 178):—Thoroughly mix 1 grm. of ore with 3 grms. of NaF or pure powdered cryolite, put in a large platinum crucible, and cover with 12 grms. of coarsely powdered KHSO_4 . Fuse about 20 minutes, cool, add conc. H_2SO_4 , fuse to homogeneous paste, cool, and dissolve in cold water. When cryolite is used, a bulky white residue of CaSO_4 generally remains. Reduce the solution obtained by either of these methods, and titrate in usual way. But if the ore contains TiO_2 , see Notes 10 and 18.

Arsenic.—Fuse 5 grms. of ore as in Main Analysis, and obtain the Water Solution, in which the As will be present as sodic arseniate. Add a little Na_2SO_4 and HCl to slight acid reaction, boil a few minutes until all the As_2O_3 has been reduced to As_2O_5 , saturate the warm solution with H_2S gas, filter, and wash with H_2S water. Dry filter and contents, and oxidise them in a beaker with fuming HNO_3 . Dilute, warm gently with a little KClO_3 , to oxidise organic matter.

Sulphuric Acid.—Boil 5 grms. ore with 50 c.c. $\text{HCl} + 50$ c.c. $\text{H}_2\text{O} + 10$ c.c. alcohol. Filter and precipitate with BaCl_2 in the filtrate. The difference between the sulphuric anhydride thus found and the total found in the Main Analysis will give the amount equivalent to the S actually existing in the ore as metallic sulphide.

Titanic Acid.—The ore must be decomposed, and the TiO_2 brought into solution in cold water by Clarke's method, described under "Ferrous Oxide." Then proceed as in Note 10.

Vanadic and Tungstic Acids.—These acids, which occur in very small quantities in some European ores, may be separated and detected as follows:—Treat Residue (a), obtained from 10 to 20 grms. of ore, like Residue (c) in the Scheme, until all SiO_2 is expelled. Any residue which remains may contain Al_2O_3 , TiO_2 , V_2O_5 , and WO_3 . Ignite and weigh, fuse it with Na_2CO_3 , dissolve in HCl , boil, add $(\text{NH}_4)_2\text{O}$ in excess, and saturate with H_2S gas. A red colour will denote the presence of V_2O_5 , and a brown precipitate that of WO_3 (*Pogg. Annal.*, 21, 47. *H. Rose's Handb. d. Anal. Chem.*, ii., 764).

Chlorine.—This occurs in ores containing apatite. Mix with Na_2CO_3 and K_2CO_3 , moisten with water, dry in the platinum crucible, fuse, boil with water, remove the dissolved SiO_2 by means of $(\text{NH}_4)_2\text{CO}_3$, and then precipitate, after addition of HNO_3 , with AgNO_3 .

Fluorine.—This occurs in ores containing apatite and fluor-spar. Decompose the ore by Berzelius's method, separate the SiO_2 , and expel the excess of $(\text{NH}_4)_2\text{CO}_3$. If P_2O_5 is present, precipitate with CaCl_2 , together with CO_2 and HF , and separate the CaCO_3 by acetic acid. In the remaining precipitate of $\text{Ca}_3\text{P}_2\text{O}_8 + \text{CaF}_2$, determine the F directly by Wöhler's method, as SiF_2 .

Organic Matter.—Roast 1 grm. in an open crucible, at a red-heat, and (when the protoxide of iron, the higher oxides of manganese, sulphur, and arsenic, are absent) the loss diminished by the amounts of carbonic anhydride and H_2O present will be approximately equivalent to the amount of organic matter.

ON THE
CHEMICAL CONSTITUTION OF GLYCOLIC
ALCOHOL AND ITS HETEROLOGUES,

AS VIEWED IN THE NEW LIGHT OF THE "TYPO-
NUCLEUS" THEORY.*

By OTTO RICHTER, Ph.D.

(Continued from p. 280).

The chemical constitution of glycolic alcohol and its heterologues may be adequately expressed by means of the following table of rational formulæ, where the non-essential constituents are separated from the essential constituents by a horizontal line. You will also understand that the various marks of punctuation used in these formulæ are typical symbols of molecular grouping. Thus, a dot connects the base with its acid; a semicolon connects the hydrocarbon adjunct with its principal; an inverted semicolon connects the halogen adjunct with its principal, and a concave curve connects two principal bases with one another. I must further say that for want of a proper nomenclature, it has here and there been found necessary to introduce new names.

Table of Chemical Formulæ Representing the Chemical Constitution of Glycolic Alcohol and its Heterologues.

	$\text{H}_{12}\text{C}_8\text{O}_8$	H_2O_2	H_2O_2
Glycolic alcohol	2C_2	H_2O_2	$2\text{H}_2\text{C}_2$
Deglycolic alcohol	2C_2	H_2O_2	2C_2
Glycolite of water	2C_2	H_2O_2	2H
Glycolate of water	2C_2	H_2O_2	2H
Oxyglycolate of water	2C_2	H_2O_2	2H

So far as I am aware, the glycolic alcohol, which is the parent molecule of this family group, has not yet been obtained in a state of isolation. The well-known ethylen-glycol might at first sight be taken for the missing alcohol, more particularly when we couple the decidedly biatomic character of their respective molecules with the other and even more significant fact that the whole of the glycolic heterologues may be produced by the simple oxidation of the ethylen-glycol. Nevertheless, and notwithstanding these striking points of resemblance, I am inclined to believe that these two alcohols are not alcohol, but only isomeric, and I ground my belief upon the occurrence of a certain class of chemical compounds among which the so-called diethyl-acetal is the most conspicuous and best investigated member. This diethyl-acetal, you will recollect, is strictly isomeric with the diethyl-ether of the ethylen-glycol, and I feel convinced that it is the missing glycolic alcohol to which we are indebted for this curious and instructive case of isomerism. A cursory examination and comparison of the subjoined rational formulæ will suffice in order to prove that my belief is well founded.

	$\text{H}_{12}\text{C}_8\text{O}_8$	H_2O_2	H_2O_2
Ethylen-glycol	$2\text{H}_2\text{C}_2$	H_2O_2	2C_2
Glycolic alcohol	2C_2	H_2O_2	$2\text{H}_2\text{C}_2$
Diethyl ether of ethylen-glycol	$2\text{H}_4\text{C}_4$	H_2O_2	$2\text{H}_4\text{C}_4$
Diethylacetal	$2\text{H}_4\text{C}_4$	H_2O_2	$2\text{H}_4\text{C}_4$

* Abstract of a Paper read before the British Association, Edinburgh Meeting, 1871.

† You will bear in mind that in my system the term "halogen" includes every species of mono- or polynormal acids, bases, or salts; and that the "empirical formulæ" used in my system are exactly the double of the ordinary formulæ. $\text{H}_2 = 1$; $\text{C}_2 = 2$; $\text{O}_2 = 1$.

You will observe that ethylen-glycol differs from glycolic alcohol in two essential points; first, in the former compound, the two alcoholic constituents are represented as playing the co-ordinate part of principal alcoholic bases, while in the latter compound one of these alcoholic bases is represented as playing the subordinate part of adjunct to the other base. Secondly, the relative positions which the two alcoholic constituents occupy in ethylen-glycol are exactly reversed in the glycolic alcohol. A mere glance at the two formulæ which express the chemical constitution of the isomeric ether derivatives will, I trust, enable the reader to complete the analysis of these hitherto obscure and unintelligible cases of isomerism. The second member in the family of glycolic heterologues is likewise very little known. I have applied to it the term "deglycolic alcohol," in order to record the fact that it is produced from the primary alcohol by the simple abstraction of two molecules of hydrogen from the methylen adjunct of the principal water base. This secondary alcohol, like the majority of the alcohols which occupy the second place in the family group of the heterologues of the fatty alcohols, seems, from its want of stability, very prone to merge into the isomeric and far more permanent modification of the glycolite of water. In this remarkable metamorphosis, the double carbon adjunct of the principal water base becomes first of all converted into an acid twin carbon nucleus, which reunites under this new form with the old water base, whereupon, under the combined influence of base and acid, the remaining water molecule becomes decomposed so as to surrender its oxygen to the envelope of the acid twin carbon nucleus, while the hydrogen connects itself with the same nucleus under the typical form of a hydrocarbon adjunct. It is worthy of note that in this singular and characteristic re-arrangement of the constituent elements, the organic molecule has, without loss of substance and without loss of saturating capacity, passed at one bound from the category of a true and genuine alcohol into the category of a true and genuine water salt. As regards the two remaining heterologues of glycolate of water and oxyglycolate of water, you cannot but see that their formation is due to the successive absorption of two molecules of oxygen by the envelope of the glycolous acid constituent, and that they differ from each other in this respect only, that the former contains for its principal constituent formate of water, while the latter contains instead of it oxyformate of water. Some of my readers may here be supposed to ask, what is oxyformate of water? Why, it is simply a highly interesting isomeric modification of the neutral carbonate of water. You are aware that on account of its excessive want of stability none of the carbonates of water can be obtained in a state of isolation. The compound before us differs from the isomeric neutral carbonate in being decidedly monobasic, while the latter is as decidedly bibasic. The cause of this apparent anomaly becomes now fully revealed, for it is plain that one of the two hydrogen molecules which, in the ordinary carbonate of water are both of them readily displaceable by metals, has assumed the hydrocarbon form of grouping, in consequence of which it will cease to play the part of a basic nucleus, and although it may become eliminated or exchanged in obedience to other modes of substitution, it is certain that the ordinary process of double decomposition has no control over it. In speaking of the deglycolic alcohol, I forgot to mention that a substance has recently been obtained by Boutlerow, and re-examined by Hofmann, who mistook it at first for the missing formic aldehyde. This curious compound, if we take the density of its vapour for our guide, ought to be represented by the same empirical formula as the deglycolic alcohol, but from its chemical deportment it will probably become identified with the glycolite of water, which I regard as the true aldehyde of the glycolic family group.

Let us now pass on to consider those interesting and singularly close chemical relations which are found to obtain between the heterologues of the glycolic alcohol on

On the one hand and the heterologues of the ethylic alcohol on the other hand. These two kindred family groups are in the subjoined table brought face to face with one another.

Heterologues of Glycolic Alcohol.

	$H_{12}C_8O_8$	$H_2O_2 \cdot$	$H_2O_2 \cdot$
Glycolic alcohol	$2C_2; H_2O_2; 2H_2C_2; H_2O_2$	$H_2O_2 \cdot$	$H_2O_2 \cdot$
	$H_8C_8O_8$	$H_2O_2 \cdot$	$H_2O_2 \cdot$
Deglycolic alcohol	$2C_2; H_2O_2; 2C; H_2O_2$	$H_2O_2 \cdot$	$H_2O_2 \cdot$
	$11_8C_8O_8$	$H_2O_2 \cdot$	$H_2O_2 \cdot$
Glycolite of water	$2C_2; H_2O_2; 2H; 2C_2O$	$H_2O_2 \cdot$	$H_2O_2 \cdot$
	$H_8C_8O_{12}$	$H_2O_2 \cdot$	$H_2O_2 \cdot$
Glycolate of water	$2C_2; H_2O_2; 2H; 2C_2O_3$	$H_2O_2 \cdot$	$H_2O_2 \cdot$
	$11_8C_8O_{16}$	$H_2O_2 \cdot$	$H_2O_2 \cdot$
Oxyglycolate of water	$2C_2; H_2O_2; 2H; 2C_2O_5$		

Heterologues of Ethylic Alcohol.

	$H_{12}C_8O_4$	$H_2O_2 \cdot$
Ethylic alcohol	$2H_4C_4; H_2O_2$	$H_2O_2 \cdot$
	$H_8C_8O_4$	$H_2O_2 \cdot$
De-ethylic alcohol	$2H_4C_4; H_2O_2$	$H_2O_2 \cdot$
	$H_8C_8O_4$	$H_2O_2 \cdot$
Acetite of water	$2H_3C_2; 2C_2O$	$H_2O_2 \cdot$
	$11_8C_8O_8$	$H_2O_2 \cdot$
Acetate of water	$2H_3C_2; 2C_2O_3$	$H_2O_2 \cdot$
	$11_8C_8O_{12}$	$H_2O_2 \cdot$
Oxyacetate of water	$2H_3C_2; 2C_2O_5$	

You will observe, firstly, that the members thus placed opposite each other differ throughout by the constant quantity of two molecules of oxygen. You will find, moreover, that the acetate of water is isomeric with the glycolite of water and the oxyacetate of water isomeric with the glycolate of water. Now, it is an established fact, that ethylic alcohol may, under favourable conditions, become oxidised into the ethylen-glycol, or possibly, in the first instance, into the glycolic alcohol; but whichever way we take it, the fact remains, and the explanation is easy. In ordinary circumstances, namely, when by the removal of two hydrogen molecules from the ethylen adjunct, the ethylic-alcohol becomes converted into the de-ethylic alcohol, the two molecules of water, which are generated in this process will simply be eliminated from the system, whereas, in extraordinary circumstances, these two molecules of water, instead of being eliminated, will appropriate to themselves two carbon molecules from the residual acetylen adjunct, whereupon the resulting methylic and formylic alcohols will instantly combine under the one or the other form of biatomic grouping. As regards the isomeric relations of acetate and glycolite of water, on the one hand, and of oxyacetate and glycolate of water on the other hand, there cannot be the slightest doubt that these isomeric compounds are mutually convertible, and it is clear, that when the acetate merges into the glycolate, two oxygen molecules of the oxalic acid constituent will unite; in the first instance, with two hydrogen molecules of the methyl adjunct so as to produce two molecules of water; these latter will then combine with the two molecules of carbon which are ceded to them by the residual formyl adjunct, and lastly, the generated formyl alcohol will connect itself as halogen adjunct with the acid twin nucleus of the residual formite of water. This explanation applies with equal facility to the conversion of oxyacetate of water into glycolate of water. The details of this process, as well as of the reverse process, whereby the glycolic heterologues remerge into the corresponding acetic heterologues, I shall leave the hearer to work out for himself. Let us now direct our attention to another highly instructive variety of isomeric changes which the acetic water salts are apt to experience

after one or two of the methylic hydrogen molecules have been displaced by chlorine, bromine, or iodine. I shall illustrate these analogous cases by means of the bromo- and bibromo-acetates of water. The bromo-acetate has the rational formula $\frac{H_2O_2 \cdot}{2H_2C_2Br; 2C_2O_3}$ and it is plain that the successive phases of the process will be as follows:—One hydrogen molecule will disengage itself from the brom-methyl adjunct, become converted into an acid nucleus, and brominised; the newly formed bromide of hydrogen will then unite with the two carbon molecules which it has acquired from the residual formyl adjunct, and in the last phase of the process the resulting bromide of formyl will unite as halogen adjunct with the acid twin nucleus of the residual formate of water. Accordingly, the end product of the reaction will be bromoglycolite of water with the rational formula—

This compound is, therefore, isomeric with its parent bromo-acetate of water.

The bibromo-acetate of water has the rational formula $\frac{H_2O_2 \cdot}{2HC_2Br_2; 2C_2O_3}$ and the reaction takes the same course precisely. Hence we ought to obtain as final product, the bibromo-glycolite of water with the rational formula

$\frac{H_2O_2 \cdot}{2C_2; H_2Br_2; 2Br; 2C_2O_3}$. This compound is, therefore, isomeric with its parent bibromo-acetate of water. From its want of stability it becomes, however, readily decomposed into bromide of hydrogen and bromo-glycid with the rational formula $\frac{H_2O_2 \cdot}{2C_2; H_2Br_2; 2C_2O_4}$. When this

bromo-glycid is in its turn subjected to successive treatment with strong bases and acids, it will give rise in the first instance to the bromoglycolate of water with the rational formula $\frac{H_2O_2 \cdot}{2C_2; H_2Br_2; 2H; 2C_2O_5}$ and in the second instance to the oxyglycolate of water with the rational formula $\frac{H_2O_2 \cdot}{2C_2; H_2O_2; 2H; 2C_2O_5}$.

DECAY OF STONE AND BRICK.

By JOHN C. DRAPER,

Professor of Chemistry, University Medical College, New York.

THE rapid disintegration or decay of the brown stone, so generally employed in the construction of New York houses, leads naturally to the consideration of the causes producing this decay, and also to the examination of other building materials, and the discussion of their merits or demerits as compared with brown stone.

The chief causes of disintegration of stone and brick are:—

- (1). Roughness of surface, favouring the deposition of dust.
- (2). Vegetable growths, favoured by dust and moisture.
- (3). Percolation of water through interstices and fissures.
- (4). Action of frost.
- (5). Action of acid vapours in the air.

In the experiments we propose to relate, the materials employed were the same as those mentioned in a previous paper, namely, brown stone, Nova Scotia stone, red brick, and white brick. Submitting these to a microscopic examination under a power of 25 or 30 diameters, a very instructive lesson regarding the structure of these materials is obtained. The stone is seen to be composed of various sized particles loosely aggregated together, and presenting a very rough surface; the red brick is smooth,

the fracture showing interstices of considerable size, while the white brick is not only smooth, but also dense, the interstices being very small; and every here and there minute spheres of molten glassy material are discoverable, showing the intense heat to which the brick has been subjected. Such a microscopic examination affords, to the architect and engineer, indications regarding the probable weathering power, which should never be overlooked in the selection of building material to be used in exposed locations, for the rough imperfectly cemented material not only favours the deposition of dust, which, being chiefly organic, furnishes a suitable nidus for vegetable growths, but it is also, by virtue of its structure, more friable, and, therefore, easily disintegrated by the forces to be considered hereafter.

The vegetable growth, of which we have spoken above, is a minute lichen, known as *Lepra antiquitatis*, and it grows with remarkable freedom on such hygroscopic rocks as the sandstones, as any one may satisfy himself on examining the houses on the cross, or east and west, streets of New York.

The percolation or passage of water takes place even in the densest rocks, as trap and basalt, for, in the interior of even the most compact specimens of these rocks, spots of moisture are often found on breaking them; and Bischoff states that these are always connected with minute fissures, the edges of which often show effervescence when they are touched with acid, thereby demonstrating that water may convey into, or produce carbonates, even in these dense rocks, and thereby alter their structure. This being the case with compact rock, we can form some idea of the manner in which percolating water acts on such loosely cemented material as the different kinds of sandstone.

Of the agents engaged in the disintegration of rock, one of the most efficient is frost. In its action, two elements are involved, namely the friability of the material and its hygroscopic power. The difficulty attending the direct application of cold in the examination of the action of frost, has led to the use of other and similar means. Among these none is better adopted for the purpose in view than that of dipping the material to be examined in a saturated solution of sulphate of soda, and allowing the salt to crystallise when the specimen has been thoroughly saturated with the saline solution. The crystallisation of the sulphate of soda, on and in that substance, brings to bear upon its particles the same kind of force as that produced in the crystallisation or freezing of water, and particles are torn off or separated exactly as in the latter operation. In employing this test I soaked the rock in the solution for about four hours, and let it dry and crystallise for twenty hours. The loosened material was washed off by a fine jet of water from a washing bottle, the sample re-dipped for four hours, and again set to crystallise. This was repeated eight times, the experiment extending over a period of eight days, with the following results:—

Table I.

Brown stone	10,000 parts lost	191 of substance.
Nova Scotia stone ..	" "	441 "
Red brick	" "	74 "
White brick	" "	24 "

The disintegration is very nearly in the ratio of 1 for the white brick, 3 for the red, 8 for the brown stone, and 18 for the Nova Scotia stone, a result which furnishes information of the greatest value from an economic point of view, and which cannot be too strongly insisted upon in a country where so little attention is paid to the durability of public and private edifices.

The long periods of time required for the performance of the crystallisation test, led me to make a series of experiments to find a quicker method of arriving at a reliable determination of the friability of these substances. The plan I endeavoured to apply was to heat the specimens to

a temperature of about 600° F., and then quench them while hot in cold water. The sudden chill and formation of steam on the surface of the masses caused them to disintegrate superficially, the amount of material removed after the repetitions of the chill being—

Table II.

Brown stone	10,000 parts lost	202 of substance.
Nova Scotia stone ..	" "	597 "
Red brick	" "	82 "
White brick	" "	43 "

Which gives a ratio of 1 for the white brick, 2 for the red, 5 for the brown stone, and 14 for the Nova Scotia. These results do not agree exactly with those given by the sulphate of soda test, but they approach them more closely than could have been expected considering the different character of the force applied.

Though the chilling test described above may be objected to as not meeting the conditions prevailing during the action of frost, but being rather the opposite, on account of the employment of heat in place of cold, it gives results which are very significant when viewed in relation to the power of brick and stone to resist the destroying action of great conflagrations. The conditions of the experiment are almost identical with those presented by a building on fire, for in each case the substance is alternately heated by the flames and chilled by the water thrown to quench them. The table, therefore, gives a very fair estimate of the relative powers of the materials in question to resist such destructive action.

The chemical ingredients of the air that act on building materials are carbonic, nitric, sulphuric, and sulphurous acids. The first of these is always present as the product of combustion, and, when dissolved in rain-water, forms a solution which readily dissolves marble and other limestones, and even acts on dense granite and other rocks. Sulphuric and sulphurous acids are both found in appreciable quantity in the air of all localities where coal is used as fuel. Nitric acid is, in its turn, at times an ingredient of the air, especially after great displays of lightning; it also is produced, under certain conditions, during the decomposition of organic matter containing nitrogen. To determine the action of these acids on the materials with which I was experimenting, I placed portions of them in dilute nitric acid, and left them in contact with the liquid for two weeks. I then kept them in water for ten days, changing the water every day to ensure the removal of all soluble material; they were then dried, and being weighed, gave the following results:—

Table III.

Brown stone	10,000 parts lost	214 of substance
Nova Scotia stone ..	" "	66 "
Red brick	" "	33 "
White brick	" "	7 "

In which the ratio of disintegration is 1 for the white brick, 5 for the red, 9 for the Nova Scotia stone, and 30 for the brown stone. From this it would appear that the reason the brown stone disintegrates so rapidly in New York is its greater susceptibility to the action of the acid products of organic decomposition and combustion, where the cementing material is dissolved or weakened, and pores and fissures in the rock being opened, it is less able to resist the attack of frost. The Nova Scotia stone, on the contrary, is a more friable material than the brown stone; yet being less acted upon by the acid waters, it resists the process of decay better. The superiority of the white over the red brick, in this respect, is even more marked than under the other tests, and, taken with them, gives unquestionable evidence of the weather-resisting power of this hard-burned compact brick.—*Scientific American*.

A REACTION OF PHENOL.

By C. CRUMP.

If a current of ordinary coal-gas be passed into a flask containing a mixture of equal parts of phenol and strong sulphuric acid, the liquid soon becomes coloured and thick, so that unless the flask be gently heated, the passage of the gas is interrupted. After a few hours, if the contents of the flask be poured into water, a red colouring matter is obtained insoluble in water, soluble in alcohol and in alkaline solutions, its colour being changed by the latter to blue or green. The formation of the colour is not prevented by previously passing the gas through dilute sulphuric acid, solution of caustic potash, or of cupreous chloride either in hydrochloric acid or ammonia, nor does the colour seem to be produced by passing any of the ordinary constituents of coal-gas into the mixture. A similar substance, however, seems to be formed by digesting the mixture of phenol and sulphuric acid for some time at a gentle heat with two or three times its volume of commercial benzol.

PROCEEDINGS OF SOCIETIES.

ROYAL DUBLIN SOCIETY.

At the evening Scientific Meeting of the Society, held on the 18th, Professor R. BALL delivered a discourse on the "Conservation of Energy," illustrated by experiments. These discourses, to which ladies have been admitted, have proved most successful. The lecturer treated his extensive and difficult subject in an able, and at the same time popular, form. He divided his discourse into five parts. 1. The different forms of energy and their mutual convertibility. 2. The indestructibility of energy. 3. The conservation of energy. 4. The distribution of energy throughout the universe. 5. The dissipation of energy.

At the conclusion of the lecture Professor Ball spoke in eulogistic terms of Sir Wm. Thomson's finite theories of the universe. In mentioning the names of those connected with his subject, the lecturer omitted, evidently by an oversight, the names of Grove and Mayer. To these illustrious names are due the first speculations as regards the connection of the various forms of energy.

The experiments were frequently novel, and were in every case perfectly successful.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, November 27, 1871.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Optical and Crystallographical Observations on the Montebrazite and the Amblygonite of Montebraz (Creuse).—Dr. Des Cloizeaux.—An exhaustive essay, illustrated by engravings.

Thermal Researches on Electrolysis.—P. A. Favre.—The continuation of the author's experiments.

Three Enormously Large Meteorites.—M. le Ministre de l'Instruction Publique.—The author states that he has received from

the French Consul at Elsenour (Danemark) a letter communicating the arrival at Copenhagen of the two Swedish men-of-war sent to Greenland, there to take on board three very large meteorites discovered in that country by the Swedish *savant* Nordenskiöld last year. By arrangement with the Danish Government, the Government of Sweden equipped the vessels to convey the meteorites to Europe. Two of these masses, weighing respectively 49,600 and 10,000 lbs., have been sent to Stockholm, while the third, weighing 20,000 lbs., has been presented to the museum at Copenhagen. The ponderous masses surpass in weight and size any meteorites yet found, excepting that the San Gregorio meteorite of the Mexican desert exceeds in weight and, in all probability, in size, the least weighty of the masses alluded to.

Separation of Potassa from Soda.—Th. Schlessing.—The contents of this paper will be translated in our columns.

New Observations on the Alternating Predominance of Nitrous and Nitric Acid in Rain-Water.—Dr. Chabrier.—The main gist of this paper is that, during calm weather and a cloudy sky, rain-water usually contains nitrous acid, while, during storms and violent commotions of the atmosphere, nitric acid prevails.

Experimental Researches on the Properties of the So-Called Drying Oils.—Dr. Sacc.—The contents of this paper agree mainly with the exhaustive researches made several years ago by G. J. Mulder, and published in a separate volume in the Dutch language. An excellent abstract of these researches is published in *Jahresbericht über die Fortschritte der Reinen, Pharmaceutischen, und Technischen Chemie* for 1865, pp. 323 to 326.

Some Facts Relating to the History of the Phenols.—Drs. Dusart and Ch. Bary.—The authors communicate the results of a series of experiments made with the view to prove that the class of bodies termed phenols and their compounds resemble in their chemical character some of the hydrocarbons they are derived from, and also, though with less strong affinity, the character of alcohols with which, if they are mixed, they form, under the influence of acids for instance, double ethers, which appear to be identical with those formed by the distillation of salicylates, and discovered by Professor Cahours.

Musical Sounds Produced by the Opening of the Safety-Valve Fitted to Air-Balloons while Ascending in the Atmosphere.—W. de Fonvielle.

Journal für Gasbeleuchtung und Wasserversorgung, No. 21, 1871.

In addition to a series of original papers relating to gas- and water-works' engineering and management, this number contains—

The Description of an Apparatus for So-Called Cold Gas Manufacture.—Dr. N. H. Schilling.—The author illustrates by a woodcut an apparatus essentially contrived for the preparation of hydrogen by the aid of iron and sulphuric acid, the gas being next forced through gasoline, and thus rendered luminous. It appears that in America, viz., the United States and the Brazilian Empire, this mode of obtaining gaslight is used in some localities, but is, after all, an expensive and by no means complete substitute for coal-gas. Dr. Philipp's carboxygen illumination is found superior and also less costly.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 17, 1871.

This number contains the following original papers and memoirs:—

Silico-Heptyl Series.—A. Ladenburg.—The silico-heptyl ether, $\text{Si}(\text{C}_2\text{H}_5)_3\text{OC}_2\text{H}_5$ is a substance not acted upon by contact with air, not decomposed when treated at 250° with alcoholic ammonia solution, and decomposed by water at a temperature of 200° . Among the products of decomposition is the body $\text{Si}(\text{C}_2\text{H}_5)_3(\text{OH})$, mixed with other substances having a higher boiling-point, and from which it was impossible to separate this substance. When the silico-heptyl ether is treated at 180° with chloroacetyl (equal number of molecules of each of these bodies) in a sealed tube, and the resulting product fractionally distilled, two substances are obtained, one of which, boiling at between 70° and 80° , was proved to be acetic ether; the other, boiling at between 142° and 145° , was, on analysis, found to consist of $\text{Si}(\text{C}_2\text{H}_5)_3\text{Cl}$, silico-heptyl chloride; exact boiling-point when pure, 143.5° ; smells like camphor; sp. gr., at 0° , 0.9249; is not decomposed by alcohol alone, but is instantaneously decomposed by aqueous and alcoholic solutions of ammonia, and by aqueous solution of nitrate of silver. By the action of liquid ammonia, the silico-heptyl chloride yields a compound, $\text{Si}(\text{C}_2\text{H}_5)_3\text{O}$, a fluid boiling at 153.5° ; vapour density = 124.3; constitutional formula, $\text{Si}(\text{C}_2\text{H}_5)_3(\text{OH})$. The author proposes for this new class of compounds the name of silicols. This substance is a carbohydrate. Triethyl-silicol is insoluble in water, miscible with ether and alcohol, and burns with a bright flame, leaving silica; smells like camphor; sp. gr., at 0° = 0.8709.

New Locality in the Urat (Russia) where Diamonds Occur.—G. Rose.—After first briefly alluding to the finding of a diamond in Bohemia about two years ago, the celebrated *savant* communicates the finding of very small-sized diamonds, not as usual among the detritus of disintegrated rocks, but imbedded in xanthophyllite, a mineral occurring in the talcose schist of Achmatowsk, near Statoust, in the Southern Urat. The researches of Drs. Jeremejew and Lissenko, at St. Petersburg, leave no doubt of the correctness of this important discovery, which is of great interest in reference to the origin and formation of diamonds, which, in the locality alluded to, as also in the Brazil, occur in so-called metamorphic rocks. The author considers that diamonds may be remnants of organic material, the great mass of which has been destroyed by the metamorphosis the

rocks, originally of so-called Neptunic origin, have undergone; but no reply can be given to the question, why in the itacolumite of the Bresil the diamond should have been formed, and in that of Silesia (Strehlen) only graphite.

Pyrocatechin Met with as a Constituent of a Living Plant.—Dr. E. von Gorup-Besanez.—While engaged with a chemical research of the leaves of *Ampelopsis hederacea* (so-called wild vine), the author found that the filtrate of a precipitate caused by acetate of lead on being neutralised with milk of lime turned first bright green, then brownish green, becoming at last nearly black, reactions exhibited by pyrocatechin. On entering more particularly into this matter, the author succeeded in extracting from 2½ kilos. of the fresh green leaves of the plant, a small quantity of a body, which in all its reactions, agreed with those of pyrocatechin, viz., solubility in water, alcohol, and ether; precipitation of aqueous solution by acetate of lead; reduction of solutions of copper and silver when gently heated; olive-green colouration with somewhat oxidised solution of sulphate of iron, and emerald-green colouration with chloride of iron, turning violet by the addition of a drop of a dilute solution of bicarbonate of soda; lastly, microscopic research exhibited perfectly defined crystals of pyrocatechin. Although this body has been discovered by Eisefeldt in Malabar kino, but not in Butea kino, it does not follow that pyrocatechin should be present in the living plant (*Pterocarpus marsupium*) from which the former kind of kino is obtained. Moreover, the preparation of the drug alluded to is by no means well known; according to Hoppe-Seyler's researches, pyrocatechin is formed from carbohydrates when heated along with water under pressure, as well as by treating the carbohydrates with alkalis. In addition to pyrocatechin, the author of this memoir found, in the leaves alluded to, bitartrate of potassa, tartrate of lime, free tartaric acid, gum, and a mixture of dextrose and levulose, the former predominating.

Lecture Experiment—The Sounds (Das Tönen) of Reciprocal Flames.—M. Ballo.—The contents of this paper cannot be well understood without the reproduction of the annexed woodcut.

Anilides of the So-Called Carbohydrates.—H. Schiff.—After first briefly referring to the researches of R. Sachse (see CHEMICAL NEWS, vol. xxiv, p. 263), and next to his own researches on the action of aniline upon glucose (*Ann. d. Chem. u. Pharm.*, cxl, p. 123; cliv, p. 30), the author further states that when equal parts by weight of anhydrous glucose and aniline are mixed and heated there is obtained, with elimination of water, a deep yellow-coloured mass, which is decomposed by water and dilute acids; in its constituents any excess of aniline can, therefore, only be removed by benzene. The composition of this glucosanilide is $C_{12}H_{11}NO_5 = C_6H_5O_4 + C_6H_5N - H_2O$. The action of aniline upon cane sugar is far more difficult, and, since it requires a temperature of from 200° to 220°, the greater part of the sugar is converted into caramel, and an impure compound is obtained. The author, therefore, caused aniline to react upon pure caramel, prepared at a temperature of from 220° to 230°; formula, $C_{12}H_{10}O_4$. At 200°, this substance dissolves readily in aniline, the excess of which having been first removed by distillation, the residue is treated with ether, yielding a brown-coloured flocculent substance readily soluble in hot alcohol. After having been purified by being treated with animal charcoal, the composition of this combination was found to be $C_{10}H_8N_2O_5 = C_6H_5O_4 + 3C_4H_5N - 3H_2O$. This body is a fusible substance, glass-like on solidifying; combines with acids, the hydrochloric forming with platinum chloride an amorphous cinnamon-brown coloured double salt, $2C_{10}H_8N_2O_5 \cdot H_2PtCl_6$. The combination between aniline and the glucose remnants (*Glycose rickstücken*) may be expressed by the following formula:—

Starch is converted into dextrose when boiled with aniline, and gum, as well as dextrose, does not yield, it appears, any definite compound with aniline, which, at 200°, does not also act upon glycerine.

Oil Contained in the Pips of Grapes and Raisins.—A. Fitz.—This very lengthy memoir is divided into the following sections:—Description of the physical properties of this oil and of its products of asaponification by means of caustic potassa; investigation of the fatty acids and the derivatives thereof; erucic and brassic acids; action of fusing caustic potassa upon erucic acid.

So-Called Glycerin-Ether.—H. von Gegerfelt.—After referring to the researches of Linnemann and Zotta on a compound resulting from the action of chloride of calcium upon glycerine, which the chemists just named state to be identical with Tollens's monallylin = $C_8H_{10}O_4$ or glycerin-ether, the author states that he discovered a substance of the same composition, by the distillation of glycerine left in a retort after the preparation of allyl alcohol. The purified substance boils at between 170° and 172°; is colourless, somewhat thick, and miscible with water, alcohol, and ether in every proportion; sp. gr., at 17° = 1.0907. Tollens's monallylin boils at 240°; sp. gr., at 0° = 1.116. Linnemann's and Zotta's compound boils between 169° and 173°. The author winds up his paper with a discussion on the rational formula to be given to these compounds, but states that, owing to not having a sufficient quantity of material, he could not finish his experiments at present, intending, however, to return to this subject.

Observation on a Paper on Bryoncin.—L. de Koninck and P. Marquart.—The authors mainly state that all they have stated in a formerly published paper on bryoncin (see CHEMICAL NEWS, vol. xxi, p. 227) is to be transferred to nitro-naphthaline and its derivatives. Researches now instituted with the root of the *Bryonia dioica* led to a negative result, and, by what the authors relate, it would appear that the chemist then (viz., at the time of communication of the first experiments) attached to the manufactory of the last-named author either made a mistake, or played them a trick, when he asserted that the material the authors experimented with and published their researches on was obtained from the root alluded to.

Some Mistakes Published in the Memoir "Mesure des Propriétés Explosives du Chlorure d'Azote," by Drs. H. Sainte-Claire Deville and P. Hautefeuille.—J. Thomsen.

Action of Hydrobromic Acid upon Mononitro-Naphthaline.—H. Baumhauer.—After first referring to his former researches on the action of hydrobromic and hydrochloric acids upon mononitrobenzol, the author proceeds to relate the results of his experiments on the action of hydrobromic acid at 105° upon mononitro-naphthaline, the substances being heated in sealed tubes. One of the two new bodies formed by the reaction did not possess basic properties, but was found to be, after having been purified, a crystalline white-coloured substance, fusing at 110°, and exhibiting a distinct reaction of bromine. The other body, a fluid, boiled at between 275° and 295°, and was also free from nitrogen, but contained bromine. The reaction differs in this instance from that which obtains with nitrobenzol. Since, in this instance, the nitro-group is eliminated, and not converted into NH_2 , the process may be illustrated by the following formula:—

If, in this manner, 2 molecules of nitro-naphthaline have been decomposed, the 2 atoms of bromine set free are sufficient to convert 1 molecule of monobrom-naphthaline into dibrom-naphthaline—

Freezing-Point of Bromine.—H. Baumhauer.—Beginning with the observation that great difference of statements exist on this point, and quoting as instances that Dr. Roscoe, in his excellent book on chemistry (German edition, 1871), states that bromine is solidified at -22°, while Dr. von Gorup-Besanez (1871) mentions -73° as the freezing-point of bromine the author has verified this matter with perfectly pure and anhydrous bromine. As result of his experiments, he finds that this haloid freezes at -24.5°, forming, not as generally stated, a lead-grey coloured, but a reddish-brown coloured, solid crystalline mass. Since, in the presence of water, bromine forms a hydrate which has a far higher freezing-point, the author thinks that the quotation -73° for the freezing-point of bromine has arisen from the fact that a hydrate of that element has been experimented with.

On Phenacetic and Fumaric Acids.—L. Carius.—The contents of this paper are to be considered as a preliminary notice; as yet the author only calls attention to the fact elicited by his researches that phenacetic acid is identical with fumaric acid. The complete results of the researches on this subject will be published later.

Chemistry at the Meeting of the Russian Savants and Philosophers at Kiew.—V. von Richter.—During the meeting of the British Association at the modern Athens, the capital of Scotland, the savants and philosophers of the Russian empire assembled in large numbers at Kiew for a similar purpose. From the contents of this lengthy memoir, it appears that chemistry was fully and creditably represented by men who are, in all respects, an honour to their country. As the brief quotations made here are to be published in more complete form at a future day, we do not enter into the details of the contents of this memoir, but we may yet mention that Kiew has been selected on account of being the centre of the highly developed beet-root sugar industry of south-eastern European Russia, as well as on account of its excellent situation and celebrated university.

Zeitschrift für Chemie von Beilstein, No. 13, 1871.

This number contains the following original papers and memoirs:—

Quantitative Estimation of Sulphuretted Hydrogen mixed with Carbonic Acid.—R. Fresenius.—A strong solution of sulphate of copper is first intimately mixed with and absorbed by pea-sized lumps of pumice-stone, and this mass dried at first gently, and afterwards heated to about 150°–160°; the dried lumps are next placed in U-shaped tubes, that placed next to the gas-evolving apparatus being partly filled with fused chloride of calcium; 14 grms. of the pumice-stone, prepared as mentioned, may absorb 0.2 grm. of sulphuretted hydrogen; the material alluded to is very useful for determining sulphuretted hydrogen and carbonic acid, the latter being, of course, absorbed by soda-lime, and the gases dried previous to reaching the absorbents in ball-soda.

Quantitative Estimation of the Tannin contained in Oak Bark.—C. Neubauer.—The author describes at length a very complicated process for the estimation of the substance alluded to, the process being based upon the fact that when a solution (infusion) of oak bark is mixed with indigo-carmin, and permanganate of potassa added, the blue colour of the indigo is destroyed simultaneously with the tannin. The process described requires several titrated liquids, viz., a solution of indigo-carmin, a standard solution of tannin, a standard solution of permanganate, and a decimal normal solution of oxalic acid. Although the process here detailed may yield very correct results in the hands of an experienced analytical and volumetric chemist, it is not well suited for technical use in tan-yards.

More Important Gravimetric Methods for the Quantitative Estimation of Arsenic.—R. E. O. Puller.—The author

compares together the process of estimation as arsenic-trisulphide, as ammonium-magnesium-arsenate, and as uranium oxide-arsenate. As regards the first-named, it may be used for the quantitative estimation of arsenic by removing any free sulphur it contains by the aid of sulphide of carbon; the precipitate (tersulphide of arsenic) may be heated without loss even to 160° . As regards the second, the author quotes its degree of solubility in various fluids: 1 part of the anhydrous salt is soluble in 2781 parts of water; 15,904 parts of a mixture of 1 part of ammonia and 3 parts of water; in 1386 parts of a solution of 1 part NH_4Cl in 60 parts of water; in 8867 parts of a solution consisting of 1 part of NH_4Cl in 7 parts of water; in 2879 parts of a mixture of 1 part of NH_4Cl in 10 parts of ammonia (sp. gr. 0.96) and 60 parts of water; in 32,827 parts of Fresenius's magnesium mixture. Dried at 100° the composition of the ammonium-magnesium-arsenate is $2(\text{NH}_4\text{MgAsO}_4) + \text{H}_2\text{O}$; carefully ignited in a current of oxygen gas the salt leaves $\text{Mg}_2\text{As}_2\text{O}_7$; the third-mentioned compound, produced by acetate of uranium in a solution of arsenic acid, is insoluble in water and acetic acid; boiling of the liquid aids the precipitation greatly, and the settling of the precipitate is greatly promoted by the addition of a few drops of chloroform; the washed and dried precipitate should be ignited in a current of oxygen, or, before ignition, moistened with some nitrate of ammonium solution; the ignited precipitate consists of $(\text{UO}_2)_2\text{As}_2\text{O}_7$; results very correct.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, October, 1871.

This number contains the following original papers and memoirs:—

Progress of the Cultivation of the Cinchona Bark.—Dr. F. A. Plückiger.—A botanico-pharmacognostical essay, exhibiting, in a clearly written style, the real value of this important subject.

Chemical Investigation of the Fruit of the Vaccinium Vitis-Idæa (the Cowberry, or Red Whortleberry).—Dr. Gräber.—The berries alluded to belong to the cranberry family, and grow wild in many parts of Europe. The berries contain in 100 parts:—Water, 85.611; soluble matter, 10.185; insoluble, viz., cellulose, pectose, &c., 4.204. The juice consists, in 100 parts, of:—(a) Organic matter, viz., free acid, hydrate of malic, 1.9750; grape sugar, 5.1850; tannic acid, 0.4760; albuminous matter, pectine compounds, and suspended fatty matter, 2.3330; (b) Inorganic matter, viz., potassa, 0.0580; lime, 0.1280; magnesia, 0.0114; peroxide of iron, 0.0186; water, 89.8750; total, 100.000. This paper contains, further, a very complete and detailed account of the method of analysis pursued by the author in this research.

Methods for the Preparation of Tartar Emetic free from Arsenic.—S. Löven.—This paper describes a series of pharmaceutical experiments made with the view to ascertain under what conditions the salt alluded to may be obtained free from arsenic, the antimonial preparation which forms the starting-point of the preparation being the black commercial sulphuret of antimony. The author found that when this compound is treated with hydrochloric acid (sp. gr. 1.17), and the mixture at first slowly heated and brought to the boiling-point, and kept boiling as long as sulphuretted hydrogen is evolved, and afterwards slowly cooled, the sulphuretted hydrogen present in the liquid causes the complete precipitation of the arsenic originally present in the crude sulphuret of antimony.

NOTES AND QUERIES.

Dehydrating Oxalic Acid.—I should feel obliged if any of your correspondents would inform me of the best mode of dehydrating oxalic acid; and also if a mixture of dehydrated oxalic acid and ether would form oxalic ether.—Q. R.

Gas-Proof Fabric.—(Reply to "L.R.C.P. Ed.")—You will find mentioned in Cooley's "Cyclopedia of Practical Receipts," under the head of "Varnish," several mixtures which will answer your purpose; well-boiled linseed oil, or a solution of caoutchouc in that fluid, are generally applied.

The Solubility of Black Silk.—I enclose two patterns of black silk, and according to one of your contributors silk is soluble in hydrochloric acid. I failed in half an hour to dissolve the black portion of both samples. The orange spot of one and green stripe of the other dissolved immediately. The black colour impedes my microscopical observations. Will the black dye impede or prevent the action of the hydrochloric acid? The determination of the composition of woven and dyed fabrics is certainly a work of great difficulty, and in the present dishonest state of trade instant detection is a desideratum. All I know about the patterns is that the dresses are said to have worn badly. Strong caustic soda breaks up the fibres transversely, and discharges much of the colour. I fail to obtain the usual appearances of silk under such treatment.—W. T. S.

3. MILLER'S INORGANIC CHEMISTRY.
4. GRIFFIN'S ALGEBRA AND TRIGONOMETRY.
5. WATSON'S PLANE AND SOLID GEOMETRY.

London: Longmans, Green, and Co., Paternoster Row.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c.; of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily.

Especially facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. E. V. G., 44, Berners-street, W.

ANALYTICAL LABORATORY and SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied and the erection of Plant and Buildings is superintended when required.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA of HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only as it warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2d., which costs us, if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar Sold by all Italian Warehousemen, Grocers, Chemists, and Ships. Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT of MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British French, Prussian, Russian and other Governments.

THE MANUFACTURE OF CHLORINE.

ALTHOUGH the development of the process for the Manufacture of Chlorine by means of oxides of manganese regenerated by means of magnesia, to which reference was made on this page some months ago, has been sorely delayed by serious ill-health on my part, I am nevertheless in a position to announce that that process, in a certain modified form which it has now assumed, has proved capable of yielding even more advantageous results than I formerly claimed for it. It will necessarily be yet some time before I can be able or free to supply working details. Meanwhile, I beg to report as follows:—

I. That the new form of process yields, in the free state, practically *all* the chlorine contained in the salt decomposed, being at about the rate of *a ton of bleaching-powder per fourteen hundredweights of salt*.

II. That, of the chlorine which it thus yields, a sufficient proportion to give a ton of bleaching-powder for about each thirty hundredweights of salt is ENTIRELY UNDILUTED, and therefore available for the manufacture of bleaching-powder in the chambers at present in use. This portion of the chlorine is generated in the ordinary (Weldon) stills, and is in precisely the same condition as that produced in my process as at present practised, or as that generated by means of native manganese.

III. That, while the remainder of the chlorine is *dilute*, it is not more so than that produced in any process yielding dilute chlorine only, and is free from carbonic acid, the sole diluent being nitrogen.

IV. That the process, in its new shape, is performed without blowing engines, and *without machinery of any kind*, by appliances already in use in every alkali-work, the only thing employed in it which has any "moving parts" being an ordinary liquor-pump.

The new form of process thus yields more *strong* chlorine, per given quantity of salt, than has ever hitherto been produced by any process whatever, and, in addition, yields the remainder of the chlorine in as good a state as the richest chlorine producible by any process which yields dilute chlorine only. While permitting the present production of bleaching-powder, per given quantity of salt, to be nearly *quadrupled*, it enables one-half of the quadrupled production to be made from undiluted chlorine, in such chambers as have been employed hitherto, and one-half of the chlorine to be generated in the present stills. Putting the whole cost of the process on the *strong* chlorine only, the cost of the latter, per ton of bleaching-powder, promises to be lower than it has ever been yet, the other half of the chlorine counting as not costing at all. Lastly, the special plant required for the new form of process is so simple and inexpensive, that the cost of a plant for any considerable production will probably not exceed £20 for each ton of bleaching-powder to be made by it per week.

WALTER WELDON.

THE CHEMICAL NEWS.

VOL. XXIV. No. 631.

NOTE ON FUCUSOL.*

By JOHN STENHOUSE, LL.D., F.R.S.

In a paper which I communicated to the Royal Society of London in 1850,† "On the Oils produced by the Action of Sulphuric Acid upon various Classes of Vegetables," after describing the sources, method of preparation, and characteristic properties of furfural, and its educts, I described another isomeric substance closely resembling furfural, both in its physical and chemical properties, and which I named fucusal from the source whence it had been obtained, namely, *Fucus nodosus*, *F. vesiculosus*, and *F. serratus*, &c.

The nature of the substance which yielded furfural was involved in considerable obscurity until the publication of Gutzkow's paper "On the Furfural-yielding Substance in Bran,"‡ which he found to be present in it to the amount of 15 to 20 per cent, and which, when boiled with dilute sulphuric acid, was converted into a brownish sweet syrup. This is the substance from which furfural is obtained by distillation with sulphuric acid or hydrochloric acid.

Fucusal.

I have found that when sea-weeds were boiled with very dilute sulphuric acid, containing about 3 per cent of acid, that a substance corresponding to that described by Gutzkow was obtained, which, when distilled with sulphuric or hydrochloric acid, yielded fucusal. In my paper of the year 1850 I have described the difference in the physical properties of furfural and fucusal, and also the difference between the products obtained by the action of ammonia upon them and the bases derived from these. I have again repeated the examination of these substances with great care, and find my former statements to be correct. In addition to these, I have recently prepared the aniline compound analogous to furfuraniline. || *Fucusaniline* hydrochlorate crystallises in needles of a magnificent purple colour, and closely resembles the corresponding furfural compound.

As is well known,§ when furfural is boiled with water and silver oxide, metallic silver is deposited and silver pyromucate formed, which remains in solution. In a similar manner I found that when fucusal was digested at 100° C. for five or six hours with an excess of recently precipitated silver oxide and a considerable quantity of water, its odour gradually disappeared, and at the completion of the reaction a silver-salt was found in solution, whilst metallic silver was deposited, partly in a granular state, and partly as a mirror, on the bottom of the flask. Sufficient hydrochloric acid was then added to the hot filtered solution to precipitate the silver. After the removal of the argentic chloride it was carefully evaporated at a temperature below 100°; and the brown semicrystalline mass thus obtained boiled with light petroleum oil, which dissolved the acid and left the colouring matter. One or two crystallisations from boiling water rendered it quite pure.

Analysis.—0.888 grm. substance gave 0.370 grm. carbonic anhydride and 0.080 grm. water.

		Theory.	Found.

* A Paper read before the Royal Society.

† *Phil. Trans.*, 1850, p. 467.

‡ *Zeits. Chem.*, 1870, p. 360.

§ *Proc. Roy. Soc.*, vol. xviii., p. 537.

§ *Ann. Chem. Pharm.*, vol. cxvi., p. 259.

From this analysis, it will be seen that this acid, which I propose to call *β pyromucic acid*, is isomeric with ordinary pyromucic acid, from which, however, it slightly differs in its physical properties. The melting-point of pure *β pyromucic acid* is 130°, being nearly the same as that of the acid obtained from furfural, which I found to be 133°, and which Schwanert* gives as 134.3°. The *β pyromucic acid* from fucusal crystallises from its aqueous solution in small rhomboidal plates, whilst the acid which I had prepared from furfural crystallised in flat needles.

Silver β pyromucate.—This compound was prepared from the pure *β acid* by boiling it for a short time with silver oxide and a sufficient quantity of water, filtering, and setting aside to crystallise. A single re-crystallisation from boiling water, in which it is only moderately soluble, rendered it quite pure. On cooling the hot aqueous solution, the silver *β pyromucate* is obtained in long flat needles, whilst the corresponding salt of the ordinary acid forms small crystalline scales; 0.505 grm. of silver-salt gave 0.330 grm. argentic chloride, which corresponds to 49.18 per cent of metallic silver. The formula C₅H₃AgO₃ requires 49.32 per cent.

From this silver determination it will be seen that this compound is isomeric with the ordinary silver *α pyromucate*, C₅H₃AgO₃.

ON THE SOLVENT POWER OF LIQUID CYANOGEN.†

By G. GORE, F.R.S.

In the following experiments a number of stout tubes of refractory glass of the annexed shape were employed

Each tube was closed at one end, and had a flanged mouth at the other. The limb A was 1½ inches long, the limb B 2 inches, and C 7 inches.

In making the experiments, each tube was first filled to an extent of 5½ inches of its length, with highly dried crystals of mercuric cyanide: a small fragment of asbestos‡ was then pushed tightly against the end of the cyanide by means of a thin rod of gutta-percha, and the bend of the tube cleaned by means of a slender brush. A number of taper plugs of gutta-percha were previously made, by softening the end of a rod of that substance in boiling water, and then chilling it; and loops of thin copper wire were also prepared for the purpose of securing the plugs.

Having placed in the bend of the tube the substance to be operated on, a plug was wetted with chloroform, and at once firmly inserted in the mouth of the tube and secured by means of the wire. A wet rag was wrapped round the limb B, and the portion of the limb C containing the cyanide was inserted in a loosely-fitting tube of copper-foil within a tube of wrought-iron about 2 feet long, supported in a nearly horizontal position with the end D the lowest.

A vessel having been previously arranged to drop cold water continually upon the wet rag, a glass screen was placed by the side of the exposed part of the glass tube, and heat was gradually applied, by means of a row of Bunsen's burners, to the part of the iron tube containing the limb C. In about four minutes liquid cyanogen began

* *Ann. Chem. Pharm.*, vol. cxvi., p. 257.

† Read before the Royal Society.

‡ This may be dispensed with if the mercuric cyanide is perfectly dry.

to form, and in about five minutes longer about 2 inches in length of the bend was filled with that liquid, and the heat was then discontinued. The temperature of the iron tube was below that of visible redness: if the heat applied was not too great the glass tube retained its original form, and might afterwards be easily removed from its casing and set aside for future examination. A white fog, and signs of a heavy vapour in the bend of the tube, always immediately preceded the formation of the liquid. In many instances some of the cyanogen retained the liquid state for several days, and even weeks, especially if the bend of the tube was kept cool by means of a wet sponge.

The cyanide employed in the experiments should be crushed to a coarse powder, and highly heated a long time, with constant stirring, until it is of a slightly brown colour, otherwise, immediately previous to the appearance of the liquid cyanogen, a small quantity of a brownish tereally liquid distils over and affects the results.

More than 130 substances, including solids and liquids, and a great variety of simple and compound bodies, were subjected to the action of the liquid; the substances were in nearly all cases as free from moisture as it was possible to obtain them. The following are the results obtained:—

Substances Soluble in Liquid Cyanogen at 60° F.—Camphor dissolved rapidly and copiously. Hydrate of chloral quickly and freely. Solid C_2Cl_6 was freely soluble. Iodine was moderately soluble, and formed a deep red liquid. Picric acid moderately soluble; the solution was yellow. White phosphorus dissolved very slowly, and to but a small extent.* Gum benzoin, also white cane sugar, dissolved slowly and sparingly. Gum assafetida and gamboge dissolved slightly, and formed yellowish liquids. Bisulphide of carbon, C_2Cl_2 and C_2Cl_4 mixed perfectly with the liquid; CCl_4 mixed less perfectly. Water was only slightly absorbed.

Substances Insoluble in Liquid Cyanogen at 60° F.—Water (nearly insoluble) would not mix with the liquid,† and produced no chemical change. Iodic acid. Fine lamp-black. Well-burned wood-charcoal (two kinds). Crystals of boron. Boracic acid. Crystals of silicon. Precipitated silica. Titanic acid. A fragment of sulphur. Selenium. Selenious acid. Tellurium. Arsenic. Arsenious and arsenic acids. Realgar. Orpiment. Antimony. Antimonic oxide. Antimonic acid. Fused fluoride of antimony. Red sesquisulphide of antimony. Bismuth. Fluoride of bismuth. The oxides of iridium and silver. Argentic nitrate, fluoride, chloride, iodide, and iodate. Mercury. Mercuric chloride. Copper. Cuprous iodide. Chloride of nickel. Iron. Muriatic. Peroxide of manganese. Fluoride of manganese. Chromic oxide. Violet chloride of chromium. Oxide and fluoride of uranium. Red oxide and peroxide of lead. Plumbic chromate. Tin. Cadmium. Sulphide of cadmium. Zinc. Tungstic and niobic acids. Oxide of cerium. Carbonate of glucinum. Aluminium. Magnesium. Magnesia. Dry lime. Anhydrous carbonate of sodium. Potassic nitrate, bromide, iodate, and fluo-zirconate. Bichromate and bitartrate of rubidium. Bitartrate of caesium. Chloride and carbonate of ammonium. Oxalate of cerium. Paracyanogen. Cyanide of mercury. Nitrocyaniide of titanium. Pyrogallie, gallic, tannic, and succinic acids. Sulphate of quinine. Alloxan. Starch. Milk-sugar. Egg-albumen. Gun-cotton. The gums ammoniac, animi, copal, dammar, elemi, galbanum, guaiacum, juniper, kowic, mastic, myrrha, olibanum, opoponax, sagapenum, seed-lac, shellac, thus, and tragacanth. Yellow resin. Egyptian asphaltum. Gutta-percha. India-rubber. Paraffine. Anthracene. Stearine. Bees'-wax. Spermaceti. Aloes—Barbadoes, Cape, hepatic, and socotrine. Brazil-wood. Red santal-wood. Cuba yellow fustic. Terra japonica.

The following substances produced some changes, but did not dissolve:—Perfectly white and dry iodic acid

made the liquid of a pink colour. Dry selenious acid and iodate of potassium became slightly pink. Yellow chloride of nickel (nearly anhydrous) became at once green.* Cuprous iodide acquired the colour of vermillion. Sesquicarbonate of ammonium became brown. The gums myrrha and guaiacum coloured the liquid yellowish. Bisulphide of carbon, saturated with sulphur, rapidly set free its sulphur in the form of crystals, the bisulphide being absorbed and dissolved by the cyanogen. A saturated solution of phosphorus in bisulphide of carbon quickly liberated its phosphorus in a similar manner, but not in a crystalline form. The contact of moisture and an alkaline substance with the liquefied gas caused the formation of a brown solid body, apparently paracyanogen.

From these results it is evident that liquid cyanogen, at 60° F., is a remarkably inert body, and possesses very little solvent power for substances in general; out of 132 substances only 14 were dissolved, and not a single one exhibited signs of strong chemical action.

ON THE ANALYSIS OF CHROME ORE.†

By JOHN CLARK, Ph.D.

IN 1862 Dr. Genth called attention to the discrepancies between his own and other chemists' analyses of chrome ore, and even at the present day there are few analyses in which, generally speaking, the results of chemists disagree to a more marked extent. In addition to the difficulty of obtaining concordant results by different chemists, the consumers of chrome ore complain that in the manufacture of bichromate of potash there is a loss of oxide of chromium which they can only account for on the supposition that the chemist generally reports too high a result.

These complaints do not appear to be altogether unfounded. Undoubtedly, many discrepancies are due to differences in the sample, but still more so to the inexperience of the analysts and the difficulty of obtaining correct results by the ordinary methods of analysis. The impossibility of obtaining by washing alone an oxide of chromium precipitate perfectly free from alkali, after fusing the ore with bisulphate of potash, was recognised by Dr. Genth, who recommended that, before weighing, the ignited precipitate should be boiled with water containing sulphurous acid, to reduce the chromate which had been formed, and that the oxide produced by the reduction should be precipitated with ammonia. By this means the weight of the precipitate of oxide of chromium is considerably reduced, but in the experiments I have made never quite pure. Instead of boiling the ignited precipitate with water containing sulphurous acid, the precipitate may be boiled with dilute acetic acid, and the chromic acid thus removed estimated with a dilute solution of double sulphate of iron and ammonia of known strength. The oxide of chromium in the form of chromate usually amounts even in the most carefully washed precipitate to 0.76 per cent. Perfectly accurate results by the precipitation method without subsequent correction can, I believe, only be obtained in the absence of sulphates, as, for example, by the process recommended by M. Clouet, manufacturer of bichrome in Havre (see *Annales de Chimie et Phys.*, 4 series, t. xvi., p. 90). M. Clouet's process consists in fusing the finely pulverised chrome ore with from five to six times its weight of pure carbonate of soda in a platinum crucible for five or six hours at a bright red heat without the addition of any oxidising agent, reducing the purified chromic acid formed with alcohol in presence of hydrochloric acid, and precipitating

* See also "Gmelin's Handbook," vol. viii., p. 147, article "Cyanide of Phosphorus."

† See "Gmelin's Handbook of Chemistry," vol. vi., p. 358.

* Probably in consequence of the presence of a trace of moisture.
† Read before the Chemical Section of the Glasgow Philosophical Society. The author not thinking the official report of his paper sufficiently clear, has requested us to publish it in full.—Ed. C.N.

the oxide of chromium with ammonia. In this case, owing to the comparatively small amount of salts present and the absence of sulphates, a perfectly pure oxide of chromium precipitate may be obtained. Although M. Clouet's method yields the correct amount of oxide of chromium, it is not well adapted for the laboratory on account of the length of time required for the complete oxidation of the oxide of chromium in the ore.

Perfectly accurate results may be obtained by the following volumetric method, which is at once simple and expeditious.

25 grs. of the finely powdered ore are intimately mixed with 200 grs. of hydrate of sodium and calcined magnesia in the proportion of five parts of hydrate of sodium to three of magnesia, and the mixture exposed in a platinum crucible to the heat of an ordinary Bunsen burner for three-quarters of an hour with the lid off, and afterwards for a quarter of an hour with the lid on. Under the influence of the hydrate of sodium and magnesia oxidation takes place at once, and is practically complete in less than an hour. The crucible with its contents is then placed in a basin containing water; the contents are washed out as far as possible with water, and afterwards with dilute sulphuric acid, which must be free from nitric acid. An additional quantity of pure dilute sulphuric acid is then added to the contents of the basin, and heat applied, when everything should dissolve (except, perhaps, a few flakes of silica). To the clear yellow solution is added a weighed quantity of double sulphate of iron and ammonia of known strength and more than sufficient for the reduction of the chromic acid. The excess of unoxidised iron is then estimated with a weak standard solution of bichromate of potash, and the amount of oxide of chromium in the ore calculated from the quantity of iron oxidised. It not unfrequently happens that a little of the chrome ore escapes decomposition, this must be filtered off after the chromic acid in solution has been estimated, and re-fused with hydrate of sodium and magnesia as before, as it is generally richer in oxide of chromium than the original ore. It may readily be supposed that soda-lime or a mixture of hydrate of sodium and lime would induce oxidation quite as readily as a mixture of hydrate of sodium and magnesia, but this is not the case. When chrome ore is heated over an ordinary Bunsen burner with soda-lime—hydrate of sodium and lime—or even with a mixture of hydrate of sodium and magnesia which has been ignited before admixture with the ore, only a trifling oxidation takes place.

The results obtained by the process which I have described seldom vary 0.2 per cent. I have had occasion to submit this process to several chemists; among others to the director of the School of Mines in St. Petersburg, who has not only expressed a very favourable opinion of its accuracy, but, as I understand, adopted it in the testing of the Russian ores.

The other ingredients usually existing in chrome ore (viz., oxide of iron, alumina, magnesia, and silica) may be estimated by the process described by Fresenius. I consider, however, that M. Clouet's method of estimating the iron, as described in the paper to which I have referred must give incorrect results, and I direct attention to this more especially on account of the formulæ which that gentleman has given to express the various proportions in which the oxide of iron and oxide of chromium exist. After fusing the ore with carbonate of sodium, M. Clouet assumes that all the alumina is soluble in water (as aluminates of sodium), and that the residue, when the ore is decomposed, consists only of oxide of iron, magnesia, and silica, so that when the residue is dissolved in hydrochloric acid, evaporated to dryness to render the silica insoluble, and filtered, the precipitate produced by the addition of ammonia to the filtered liquid will be pure oxide of iron, which may be collected, washed, dried, ignited, and weighed. This, so far as I understand from his paper, is the method which M. Clouet employed in

estimating the iron, although he mentions that the iron might also be estimated by a standard solution of permanganate of potash. By this method of analysis M. Clouet finds that all the varieties of chrome ore he has analysed have a definite chemical composition, and contain the oxide of chromium and oxide of iron in definite proportions after deducting the silica, alumina, and magnesia, which he regards as the matrix of the true ore.

In a number of analyses which I have made by M. Clouet's method I was never able to render the alumina completely soluble in water by fusion with carbonate of sodium, but always found a considerable portion of the alumina in the precipitate which M. Clouet regards as pure oxide of iron, and in numerous analyses of chrome ore which I have made very few of them would be represented by any of M. Clouet's formulæ. Unfortunately, I am not aware of the localities from which my samples were derived, but I do not think it will be out of place to mention the average results which I obtained.

In seventeen analyses of ores containing from 30 to 40 per cent of oxide of chromium, the average amount of protoxide of iron was 15.4 per cent.

In twenty-three analyses of ores containing from 40 to 50 per cent of oxide of chromium, the average amount of protoxide of iron was 14.3 per cent.

In thirteen analyses of ores containing from 50 to 60 per cent of oxide of chromium, the average amount of protoxide of iron was 15.0 per cent (the lowest amount of oxide of iron being 10.6, and the highest 23.14 per cent).

In each case the iron was estimated in the ammonia precipitate by a standard solution of bichromate of potash after reduction with stannous chloride.

I am not prepared to say that the protoxide of iron and oxide of chromium do not exist in definite portion, but if so, then other formulæ in addition to those given by M. Clouet will be required to express their composition.

NOTE ON THE ESTIMATION OF OXIDE OF CHROMIUM IN CHROME-IRON ORE, AND ON THE ANALYSIS OF THIS MINERAL.

By HUGO TAMM.

As I have had much practice and experience in the analysis of chromium ores from all parts of the world, this induces me to discuss Dr. Clark's paper on the same subject, read before the meeting of the Glasgow Philosophical Society of the 4th of December, 1871, and published in the *CHEMICAL NEWS*, vol. xxiv., p. 286.

1. Dr. Genth's observation must have been corroborated by every chemist. It is impossible to obtain oxide of chromium free from alkaline salts by mere washing, after fusing chrome ore with bisulphate of potash, nitre, or a mixture of nitre and carbonate of potash; and in general the presence of alkaline salts is the chief cause of error in the estimation of the percentage of oxide of chromium, which, on that account, is usually reported as too high.

2. A second and not less important cause of error is due to the invariable presence of silica, alumina, and a little oxide of manganese, in the precipitated oxide of chromium, contributing also to the too high result.

3. Dr. Genth's and Dr. Clark's suggestions, relative to the use of sulphurous and acetic acid, are practically of no value.

4. Clouet's process has all the disadvantages inherent to the general process, plus the length of time required by his way of oxidising.

5. If, as Dr. Clark says, one part of chrome ore is thoroughly oxidised in less than an hour by 8 parts of soda and magnesia, this process will prove valuable for the

mere assaying of chrome ores, but it is most objectionable in the case of an analysis, for magnesia is one of the constituents of chrome-iron ores, and, besides, it is difficult to separate from most substances. On the other hand, it is difficult to find caustic soda free from silica and alumina.

The following process, which I have used with advantage, overcomes the difficulties inherent to the analysis of chromium ores:—

(a.) Bisulphate of potash is the substance by which chrome-iron ore is most readily attacked; consequently the ore is fused with 15 parts of pure bisulphate of potash, and when the action is over the mass is brought to a bright red-heat, to drive off the excess of sulphuric acid.

The sulphate of chromium thus obtained being insoluble in water and in acids, a mixture of 10 parts of nitre and 10 parts of pure carbonate of potash is thrown in the crucible, and the whole mass is fused and stirred.

In this operation the whole of the oxide of chromium is readily converted into chromate of potash.

The crucible and its contents are thrown into water, and when the disintegration and solution are complete the solution is separated by filtration from the insoluble precipitate, which is then submitted to analysis, and is found to contain, in general, oxide of iron, silica, alumina, magnesia, lime, and a little oxide of manganese.

(b.) The alkaline liquor contains chromic acid, silica, alumina, and a little oxide of manganese.

A piece of litmus paper is introduced in the solution, which is well stirred with the left hand, while with the right hand hydrochloric acid or nitric acid, previously placed in a beaker, is rapidly poured in the alkaline liquor until the litmus paper turns red. This being done, and without a moment's interruption, ammonia, previously placed in a beaker, is thrown in the liquor in sufficient quantity to turn the litmus paper blue, and some carbonate of ammonia is then added. By this means silica, alumina, oxide of manganese, and generally a very small proportion of oxide of chromium, are precipitated.

The success of this most important operation depends on the rapidity with which the alkaline liquor is first acidulated and then neutralised. It is absolutely necessary to perform this operation as rapidly as possible, because, on addition of an excess of acid, nitrous acid is evolved, and if ammonia was not used instantly to saturate the acids, a considerable proportion of chromic acid would be reduced.

(c.) The liquor is filtered, and thus separated from the source of error,—silica, alumina, &c.,—and the chromium existing in this liquor has only now to be separated from alkaline salts to be obtained perfectly pure.

To effect this object the liquor is acidulated with a large excess of hydrochloric acid. Nitrous acid is evolved, and chromic acid is rapidly reduced to the state of oxide. When the reduction is complete water is added, and then an excess of ammonia, and the whole is boiled. A large excess of chloride of ammonium has been formed, and it is this salt which assists mostly in the separation of oxide of chromium from alkaline salts. The oxide is washed three or four times by decantation. This oxide is not quite free from alkaline salts, sulphates especially. It is absolutely necessary to dissolve it a second time in a large excess of hydrochloric acid, and to re-precipitate it a second time by ammonia, and to wash it until the washings are free from sulphates or fixed salts.

This second operation, which is indispensable, is most efficient, and the oxide then obtained is practically free from alkaline salts.

If we consider (1) that by this process the correct amount of oxide of chromium can easily be estimated in the course of 6 or 7 hours, (2) that the oxide of chromium obtained is quite pure, (3) that all the other substances accompanying chrome oxide may easily be determined and estimated, we must arrive at the conclusion that this process is one of the best that can be proposed.

ON THE

SOLUBILITY OF SOME FORMS OF PHOSPHATE OF LIME.*

By CHARLES P. WILLIAMS,
Director of the Missouri School of Mines.

AGRICULTURAL experience has long appreciated the difference in the rapidity of action of ground bones on the one hand and of some of the phosphatic guanos on the other. The decided preference given to the first form of phosphate of lime and to the various manipulated guanos and so-called superphosphates is not merely the result of prejudice, but is in exact accordance with the results obtained by chemical experimentalists, who have shown that the solubility of tricalcic phosphate in water containing carbonic acid is as various as the source from which it is obtained. Bischoff has shown† that while one part of apatite will dissolve in 393,000 parts of water saturated with carbonic acid, the artificially prepared basic phosphate requires only 1102 parts of the same for its solution. As theoretical considerations would appear to indicate that all forms of phosphate of lime must pass to a condition corresponding to that of the artificially precipitated phosphate before assimilation by vegetation, the rapidity of the action of carbonic acid water in rendering phosphates soluble becomes an indication, measurably, of the relative rapidity of their action when applied as fertilisers, and hence of their comparative values in such capacity. Analytical investigations in this direction would seem to be of more immediate practical value than the simple quantitative determination of the constituents of a phosphatic guano or fertiliser, and may yet serve to harmonise some of the apparent discrepancies now obtaining between the results of the laboratory and the farm. Condition of molecular aggregation, determined by solubility in carbonic acid water, is of at least equal importance as percentage richness in phosphate of lime, and a rapid and reliable analytical method that may discriminate between such conditions of aggregation in superphosphates is a desideratum alike to chemists, manufacturers, and farmers. Justice to all parties concerned makes it imperative that the analyst of an artificial phosphatic guano should distinguish between the original insoluble phosphate of lime and that which has become such by reactions in the article in question; and until this is done the analytical estimations of soluble and insoluble phosphoric acid fall short of furnishing fully reliable data for estimating commercial value. And this is equally true of natural or unmanipulated guanos.

The writer has endeavoured to determine the solubility of some of the best known forms of natural tricalcic phosphate by operating in the following manner:—

A weighed amount of the finely pulverised material was placed in a measured quantity of water (1000 cubic centimetres), and carbonic acid gas passed through the same for fifty hours at a temperature of 60° to 70° F. At the end of this time the liquid was filtered off, nitric acid added to strong acid reaction, the solution concentrated by evaporation, and the phosphoric acid separated by means of molybdate of ammonia. The precipitate thus obtained was treated in the usual manner to convert the phosphoric acid into ammonio-magnesian phosphate, care being taken to allow the solutions in which this was forming to stand at least twelve hours before filtration. To avoid loss, the ammonia water used for washing was in all cases made of uniform strength; the amount used in each analysis was measured, in connection with its proper filtrate, and for each 54 cubic centimetres of the liquor 0.001 grm. was added to the weight of the pyrophosphate of magnesia obtained. This correction for the solubility of ammonio-magnesian phosphate in ammoniated

* Communicated by Dr. Wahl. From advance-sheets of the *Journal of the Franklin Institute*.

† "Elements of Chemical and Physical Geology," Cavendish Edition, vol. iii., p. 27.

water was made in all cases. To render the conditions of the experiments as nearly as possible uniform, the amount of phosphate of lime present was made identical in each case, an analysis of the sample being previously made and a proportionate increase or decrease of amount being taken to correspond to increased or decreased percentage of phosphate of phosphate of lime.

Experiment 1.—Apatite from near Perth, Canada, containing 89.27 per cent 3CaOPO_3 . Amount taken, 0.5 gm. Solution gave 0.0021 gm. PO_5 , equivalent to 0.0045 3CaOPO_3 . This amount corresponds to one part of the phosphate of lime of apatite dissolved in 222,222 parts of water saturated with carbonic acid.

Expt. 2.—Same as in No. 1, but the material levigated. Solution gave 0.0032 gm. phosphoric acid, equivalent to 0.0071 gm. 3CaOPO_3 or one part in 140,840 parts of water saturated with carbonic acid.

Expt. 3.—Fine ground and pure bone containing 56.78 per cent of phosphate of lime. Amount taken, 0.733 gm. Solution gave 0.0804 gm. phosphoric acid, equivalent to 0.1753 gm. phosphate of lime. One part of the phosphate of lime in raw bones dissolves in 5698 parts of water saturated with carbonic acid. According to Bischoff* fresh ox-bone shavings require 460 parts, while Liebig† says only 1500 parts of carbonic acid are required.

Expt. 4.—To determine whether the organic matter of the bone had any influence on its solubility, a portion of the material used in Expt. 3 was calcined and the organic matters burned off. The ash corresponded to 6.13 per cent of the original bone, and therefore contained 92.88 per cent of tricalcic phosphate. Amount of bone-ash taken, 0.4805 gm. Solution gave 0.0569 gm. phosphoric acid, equivalent to 0.1246 gm. phosphate of lime, or one part in 8029 parts of water saturated with carbonic acid.

Expt. 5.—A sample of adulterated bone dust of commerce, containing 24.32 per cent organic and volatile matters, 35.06 per cent phosphate of lime, and 26.13 per cent of sulphate of soda (salt cake with a small amount of acid sulphate). Amount taken, 1.3157 grms. Solution gave 0.1111 gm. PO_5 , equivalent to 0.2426 gm. 3CaOPO_3 —or one part in 4122 parts carbonic acid water. The greater solubility of this sample is, in all probability, due to the formation of some acid phosphate of lime

by the small amount of free sulphuric acid present in the salt cake with which it was adulterated.

Expt. 6.—South Carolina phosphate, from the property of the Charleston Mining and Manufacturing Company, containing 57.89 per cent phosphate of lime. Amount taken, 0.771 gm. Gave PO_5 , 0.0647 gm., equivalent to 0.1413 gm. 3CaOPO_3 , or one part in 6983.

Expt. 7.—Same as Expt. 6, but levigated; gave 0.1528 gm. 3CaOPO_3 , or one part in 6544.

Expt. 8.—Phosphatic guano from Orchilla Island. Containing—Moisture, 12.88 per cent; organic and volatile matters, 14.60 per cent; 3CaOPO_3 , 49.67 per cent; CaOCO_2 , CaOSO_3 , sand, clay, &c., 22.76 per cent. Amount taken, 0.8970; gave 0.0588 PO_5 , equivalent to 0.1243 gm. 3CaOPO_3 , or one part in 8009 parts of water saturated with carbonic acid.

Such well-known guanos as the Navassa and Swan Island were not experimented with on account of their larger percentages of phosphates of iron and alumina.

It is not claimed that these results will indicate the absolute degree of solubility of the several materials in the soil when the water is not saturated with carbonic acid and where there are so many modifying and controlling conditions, but they serve to indicate, with some degree of exactness, the relative rapidity of action of the different forms of phosphate of lime, and to show the wide range of solubility of the compound under similar conditions, according to the source from which it is obtained. They, perhaps, rather enhance than decrease the difficul-

ties in the way of discriminating between the chemically precipitated and the original undecomposed phosphates of a "superphosphate" by throwing suspicion on the absolute exactness of all those methods of separation based upon solubility in weak or organic acids, unless, indeed, the operator is acquainted with the raw materials employed by the manufacturer of such "superphosphate." They and all similar experiments, however, fix the great value of this precipitated or "returned" phosphate, by showing how much more rapid it is in its action than is any form of phosphate, to whatever degree of fineness it may be brought by purely mechanical means of subdivision.

SEWAGE AS A FERTILISER OF LAND, AND LAND AS A PURIFIER OF SEWAGE.*

By J. BAILEY DENTON, C.E., F.G.S.,

Hon. Member of the Royal Agricultural Societies of Norway, Sweden, and Hanover.

HAVING recently appeared as a correspondent of the *Times* on the sewage question, it may very reasonably be assumed that I have exhausted the subject, as far as I am personally able to do so; but the fact is, that having in the letters to which I refer explained the advances made by the chemist and the engineer, and shown that there has prevailed, up to this time, a disregard of the properties of different soils for the retention of the fertilising ingredients of sewage, and the purification of the water with which the sewage is mixed, I left the subject where I considered the agriculturist should take it up. Hence my appearance before our Society, at a season when many of its members connected with agriculture will be in London.

I will promise to condense the remarks I have to make as much as possible, in order that there may be sufficient time for the expression of opinions which I shall do my best to challenge.

Though large figures have been put forth, by sundry writers and speakers, of the immense loss this country suffers by casting the sewage of its towns into the rivers, and everybody acknowledges, not only that such waste ought not to continue, but that our rivers should be restored to their original purity, we have not yet brought to practical test the value of sewage to the farmer and the market gardener. Chemists have done their best to rouse public attention to the loss we suffer, and it now remains with the country to adopt those measures which will best conduce to its recovery.

Large as the intrinsic value of the fertilising matter has been shown to be by the chemist, the value of the water in which it is contained has been excluded from his consideration, though farmers and gardeners alike are prepared, after the experience of the recent years of drought, to put a high value on water for its own sake, irrespective of the fertilising elements it contains after sewage has been mixed with it, for they know how serviceable is timely moisture to the germination of seed, and for reviving and sustaining plant growth, independently of its special power of conducting to the roots of plants, in the most acceptable way, those fertilising ingredients which the chemist has valued so highly.

Hitherto, the benefit to be gained by a command of water has been more than counterbalanced by the disadvantages of excess, and the obligation of disposing of the liquid sewage at all times and under all conditions. In referring to water, therefore, I do so only to remark that, large as the theoretical value of the manurial properties of sewage has been declared to be, it may yet bear an increase when the practical mind of the agriculturist is brought to bear on its utilisation, and the dis-

* *Loc. cit.*

† Quoted by Bischoff, *loc. cit.*

* Read before the Society of Arts, December 6, 1871.

advantages under which a new branch of industry always suffers are overcome.

A High Standard of Purity of Water Essential.—But so slow and so naturally sceptical, in respect of new appliances, is the agricultural mind, that we must not wait for the recognition of the cultivator as the only thing necessary for the development of the value of sewage. We must rather trust to the obligation which will before long be imposed on all sewer authorities, so to treat the liquid refuse of towns that the effluent liquid shall conform to a recognised standard of purity; for it will only be by the most stringent enforcement of the law in this respect that all the manurial properties of sewage will be rendered available for re-production.

Taking this view, I think it is much to be regretted that the Conservators of the Thames have, without pledging themselves to any positive decision, recognised a standard of purity* in some degree inferior to that suggested by the present Rivers Pollution Commissioners in their first report, and that they have done so in the face of a statement by the Commissioners, that they made the suggestion with the "belief that, as science progresses, improved methods of purifying polluted liquids will be discovered, and that eventually standards of purity considerably higher than those recorded may, if necessary, be enforced." Without presuming to give any opinion upon the details of the standard suggested by the Commissioners, which I know is regarded by some chemists as objectionable, I am content to record the fact that their anticipation has already been in a measure realised. This is not mere assertion; it has been conclusively shown that when natural soil is so prepared, by properly designed deep drainage and deep surface cultivation, that the whole of the sewage distributed upon its surface is absorbed and percolates *evenly* through the soil, the effluent liquid passes into the arterial outfalls from the under-drains purified to a very high degree, and unobjectionable in every respect. Such, in point of fact, appears to be the purification effected by oxidation, resulting from the aeration of drainage and the intermittent use of soil for filtration, that it is not at all too sanguine view to take, that, with increased experience, we may arrive at a power of restoring water with which sewage has been mixed to its original potable condition.

For the convenience of those interested in the matter, I here give the standard suggested by the Rivers Pollution Commissioners, and will add that which has been circulated by the Thames Conservators. The Commissioners suggest that the following liquids be deemed polluting, and inadmissible into any stream:—

(a). Any liquid containing in suspension more than three parts by weight of dry mineral matter, or one part by weight of dry mineral matter in 100,000 parts by weight of the liquid.

(b). Any liquid containing in solution more than 2 parts by weight of organic carbon, or 0.3 part by weight of organic nitrogen in 100,000 parts by weight.

* The following notes to and from Captain Bursat, the Secretary of the "Thames Conservancy, will explain the position of this particular question at the present moment:—

"Steneage, 24th November, 1871.

"DEAR SIR,—I presume I am right in assuming that the standard of purification recommended by Drs. Frankland and Letheby, and Professor Odling is that which your Board of Conservators recognise as sufficient to regulate the influx of liquid sewage from towns on the banks of the Thames. When answering this question, would you kindly tell me whether the standard applies equally to the towns above Hampton as below.—I am, dear Sir, yours faithfully,

(Signed)

"J. BAILEY DENTON.

"Captain Bursat, Thames Conservancy."

"Thames Conservancy Offices, 41, Trinity Square, Tower Hill, E.C., 1st December, 1871.

"DEAR SIR,—In reply to your letter of the 24th ult., I beg to inform you that the Conservators do not recognise any standard of purity for effluent water from sewage from places on the banks of the river above Teddington.—I am, dear Sir, yours faithfully,

"E. BURSAT, Secretary.

"J. Bailey Denton, Esq., Orchard Court, Stevenage, Herts."

(c). Any liquid which shall exhibit by daylight a distinct colour when a stratum of it 1 inch deep is placed in a white porcelain or earthenware vessel.

(d). Any liquid which contains in solution, in 100,000 parts by weight, more than two parts by weight of any metal except calcium, magnesium, potassium, and sodium.

(e). Any liquid which, in 100,000 parts by weight, contains, whether in solution or suspension, in chemical combination or otherwise, more than 0.05 part by weight of metallic arsenic.

(f). Any liquid which, after acidification with sulphuric acid, contains, in 100,000 parts by weight, more than 1 part by weight of free chlorine.

(g). Any liquid which contains, in 100,000 parts by weight, more than 1 part by weight of sulphur, in the condition either of sulphuretted hydrogen or of a soluble sulphuret.

(h). Any liquid possessing an acidity greater than that which is produced by adding two parts by weight of real muriatic acid to 1000 parts by weight of distilled water.

(i). Any liquid possessing an alkalinity greater than that produced by adding 1 part by weight of dry caustic soda to 1000 parts by weight of distilled water.

The following standard of purity for defecated water is that recommended by the chemists consulted by the Thames Conservators, and it will be seen that it is, as I have stated, less stringent than that suggested by the Rivers Pollution Commissioners. They say:—(1). It should be free from an offensive odour. (2). It should be free from suspended matters, or, in other words, be perfectly clear. (3). It should not be alkaline to turmeric paper, nor acid to litmus paper. (4). It should not contain per gallon more than 60 grs. of solid matter dried at 260° F. (5). It should not contain more than three-quarters of a grain of organic and ammoniacal nitrogen per gallon. (6). It should not contain more than 2 grs. of organic carbon per gallon. (7). It should contain not less than 1 cubic inch of free oxygen in a gallon." It should be observed, however, that one of the eminent chemists who signed this recommended standard, Dr. Frankland, being himself a member of the Rivers Pollution Commission, added these words:—"The conditions under which fluid which has been contaminated with sewage may be admitted into the Thames, as prescribed in the foregoing report, will, I have every reason to believe, preserve the river from being offensive to the inhabitants upon its banks; but, whilst thus far agreeing with my colleagues, I wish it to be distinctly understood that, in my opinion, such fluid can only be safely admissible into the Thames on condition that the water is not afterwards used for domestic purposes."

The conservators of the River Lea, in the absence of any standard recognised by the Government, have hitherto abstained from issuing one of their own, and the consumers of water in the metropolis are to be congratulated that they have done so, for the publication, limited though it has been, of the lower standard recommended to the Thames Conservators has already had the effect of encouraging results inferior to those which are to be desired. The Lea Board reserves to itself judgment until the towns discharging into the river have completed their purifying works, for which they have extended the time, at the expiration of which it is to be hoped that some positive action towards the establishment of standards to fit different circumstances will have been taken by the Central Local Government authority. Until such is the case, we shall probably see, both on the Thames and on the Lea, the sewer authorities of towns disregarding, naturally enough, the higher standard of the Rivers Pollution Commissioners, and in spite of the protest of Dr. Frankland, and the general sense of the country, the inhabitants of London may be compelled to drink polluted water, and as a natural consequence, the contamination of our streams will continue throughout the length and breadth of the land.

This point, however, is not that upon which I desire to dwell. It is of sewage as a fertiliser of land that I must speak, though it is right to repeat emphatically, what must be manifest to every practical mind, that so long as the pollution of rivers is permitted in a modified degree, by the recognition of any standard of inferior character, the fertilising ingredients of sewage will not be wholly recovered from the water with which they are mixed.

Sewage as a Fertiliser of Land.

To show what is the intrinsic value of the fertilising ingredients of sewage I will, in the shortest manner possible, state the conclusion to which Messrs. Lawes and Gilbert came in 1865, in their very complete and careful paper on the "*Composition, Value, and Utilisation of Town Sewage*" read before the Chemical Society, and which, I believe, expresses pretty accurately views in which the majority of those who are competent to deal with the subject concur. Having adopted the case of Rugby as a fair sample of water-closet towns, the discharged sewage being equal to 36 gallons per diem, or 60 tons per head per annum, including surface and subsoil waters, they stated that, "looking to the average results of 93 analyses," they found "that the sewage contained about 87½ grs. per gallon of total solid matter, of which about two-thirds was inorganic, and one-third organic. About half the total solid matter was in suspension, and half in solution; of the half in suspension, about four-sevenths was inorganic, and three-sevenths organic, and of the half in solution about four-fifths was inorganic, and one-fifth organic. Lastly, of the nitrogen, reckoned as ammonia, about one-fourth was in suspension and three-fourths in solution. The mean of the ninety-three analyses showed about 6½ grs. of ammonia per gallon, indicating a value of 1½d. for the total constituents in 1 ton of sewage." These figures, multiplied by the 60 tons of sewage per head per annum, resulted in showing "that 12½ lbs. of ammonia were contributed annually for each average individual of the mixed population of both sexes and all ages." This quantity of ammonia, at 8d. per lb., gives 8s. 4d., or 100 pence, as the value of sewage per head from water-closet towns. Various other estimates have been made of the sewage of water-closet towns. Dr. Letheby took samples at noon and at midnight, from a number of sewers in the metropolis, and arrived at the conclusion that 7·24 grs. represented the mean quantity of ammonia per gallon. Messrs. Hofmann and Witt, having treated one particular sewer, considered that 8·21 grs. represented the quantity of ammonia. These two quantities would, if taken at the same price of ammonia, result in larger figures than those of Messrs. Lawes and Gilbert.

There have been several estimates made of the value of sewage, by modes of computation differing from that based on the whole sewage of towns as discharged by the sewers, and as they will assist us in considering what proportion of the excrementitious matter of the closet may be kept out of the sewers, with benefit to agriculture and profit to the ratepayers of sewered districts, I will shortly refer to them. Messrs. Hofmann and Witt, and Dr. Thudichum, having ascertained the amount of urine and fæces voided by individual persons, taking an average of both sexes of all ages, valued the urine at 7s. 3d. and the fæcal matter at 1s. 2½d., which together, it will be observed, is very nearly the same amount as that put upon the whole sewage by Messrs. Lawes and Gilbert.

There is an anomaly in these estimates which has to be reconciled, inasmuch as it appears that the excrements of human beings alone, exclusive of the refuse from slaughter-houses, stables, cow-houses, and dog kennels, as well as that discharged from the kitchen, with its refuse of vegetable and animal food, is more valuable than the whole liquid refuse of a town, when the contents of the closet are discharged into the sewers as well as

altother refuse. And the anomaly becomes more difficult of reconciliation when we have to consider a statement by the Rivers Pollution Commissioners to the effect that, comparing water-closet towns, in which the whole of the sewage issues from the sewers, with "midden" towns, in which a considerable portion of the human excreta is detained and disposed of separately, there is a remarkable similarity of composition between the two.

I will not detain you by any endeavour to reconcile these analyses and statements, but will only remark that, assuming them to be correct, an important consequence follows, viz., that, in an agricultural view, it is desirable to treat the excremental contents of privies separately, for if no appreciable loss of fertilising matter is found to exist in liquid sewage when separated from that of the privies, it is manifest that a decided national gain is obtained by the maintenance of the two systems, inasmuch as the dry, portable manure obtained from the privy contents will be so much fertilising matter available for distant lands, in addition to the liquid sewage, which may be utilised by irrigation near at home.

But the realisation of the fertilising value of sewage in the liquid state depends necessarily upon two precedent conditions, the first being the obligation which should be imposed on all towns by the central local government authority, to perfectly cleanse their sewage; and the next, the preparation by the sewer authorities of the land designed to receive the sewage, in such a way that the whole may be fully utilised. With these two duties performed, and not otherwise, there is a fair prospect of at least a penny a ton being realised for liquid sewage of average strength, half of which (as I have stated on former occasions) should go into the pockets of the ratepayers, in repayment for the necessary works, while the other half will be due to the cultivator as a return for his industry and the employment of his capital.

Excluding from consideration the value of the water, which, I contend, will become a great item in the profitable treatment of sewage, the subject before us may be classified under three heads, viz.—(1) Where the whole of the sewage is treated by chemical process at the mouth of the sewer. (2) Where it is transported from the sewer mouth to land for distribution there. And (3) Where a part of the excrementitious refuse is treated separately from the remainder. The question which addresses itself, therefore, to the authorities of all sewered districts is, which of these methods of treatment will best enable them to effect the twofold object of purifying the sewage and utilising it to the greatest advantage; while the question which the agriculturist has to consider is, which method will place at his command, at a fair price and in the most productive shape, the fertilising matter which the sewer authorities must extract in order to cleanse the sewage perfectly.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 21st, 1871.

Dr. WILLIAMSON, F.R.S., Vice-President, in the Chair.

AFTER the minutes of the previous meeting had been read and confirmed, Mr. William Gray and Mr. Reginald C. Woodcock were formally admitted as Fellows of the Society.

The names of the following gentlemen were read for the first time:—Benjamin P. Medcalf, William H. Chandler, Charles F. Chandler, Ph.D., and John Watts, D.Sc.

For the third time—William W. Abney, Jonathan Ingle Calvert, Christopher Childs, B.A., and Frederick J. Montague Page, who were balloted for and duly elected.

The CHAIRMAN having announced that the distinguished Italian chemist, Professor Canizzaro, had consented to deliver the Faraday Lecture, called upon Mr. Henry Bassett to read his paper on "*Eulyte and Dyslyte*."

Mr. BASSETT first gave the method employed to obtain these two substances which had already been briefly described in 1851 by Baup. Citraconic acid prepared by the dry distillation of citric acid, when treated in small portions at a time with strong nitric acid, yielded an oil which solidified to a crystalline mass on standing. This product consisted of a mixture of the crystalline compounds eulyte and dyslyte, contaminated, however, with a small quantity of a yellow oil. The *eulyte*, which can only be separated with difficulty, is more soluble in alcohol than the *dyslyte*. It crystallises from warm chloroform in large prisms, melting at 99.5° (cor.), the results of its analyses corresponding to the formula $C_6H_6N_4O_7$. Submitted to the action of tin and hydrochloric acid it gave large quantities of ammonium chloride, together with a small quantity of a tarry matter, soluble in potash, with the evolution of an odour of picoline. In one experiment the author obtained indications of a solid basic substance, but the material at his disposal was too small to enable him to determine its nature. *Dyslyte*, $C_6H_6N_4O_6$, is less soluble in alcohol than eulyte, crystallising therefrom in fine long needles, which melt at 180° (cor.). The yellow oil, separated from the mother-liquors and purified by distillation in a current of steam, had the characteristic odour of volatile nitro-compounds, and exploded when heated. It is the author's intention to further investigate the nature of these compounds as soon as he has sufficient material at his disposal for that purpose.

In reply to a question put by the Chairman as to what were the properties of the compounds he had described, whether acid or basic, Mr. Bassett said that he agreed with Baup, who described them as neutral substances, for, as far as he had been able to ascertain, they were not possessed either of acid or basic properties.

Dr. DEBUS having enquired as to the comparative amount of these substances obtained from citric acid, and also what was the precise action of reducing agents on them, Mr. Bassett stated that he had distilled 30 lbs. of citric acid, and had only obtained about 50 grms. of the substances; but from the experience he had gained in the method of preparing it he hoped to be able in future operations to obtain a larger yield. In acting upon them by reducing agents almost the whole of the nitrogen was eliminated as ammonia when the reduction was complete, only a small proportion of the nitrogen being found in the tarry product; the solid basic compound he had mentioned being formed before the reduction was entirely finished.

Dr. H. E. ARMSTRONG then read the following paper:—"The Nitration Products of the Dichlorophenol-sulphonic Acids," No. IV.

The author first remarked that the action of nitric acid on the sulpho-acids prepared by treating dichlorophenol melting at 103°, which would indicate that this sulpho-acid was only isomeric with those obtained by the chlorination of the meta- and para-phenol-sulphonic acids, as these yielded chloronitrophenols melting at 121.5° and 125°, corresponding respectively to dinitrochlorophenols melting at 80.5° and 111°. When, however, the potassium salt of the sulpho-acid obtained by acting on dichlorophenol with chlorhydric sulphate, SO_2OHCl , was treated with nitric acid, the sole product obtained was invariably the nitrodichlorophenol melting at 121.5°, even under varying conditions of temperature and strength of acid. From former observations which the author has made he believes that the acid formed by the action of SO_2OHCl is dichlorophenol *meta* sulphonic acid, and hopes to be able to obtain the phenol-metasulphonic acid from it by the action of nascent hydrogen. The difference in the results obtained by the nitration of the two acids prepared from dichloro-

phenol by the action of sulphuric acid and chlorhydric sulphate respectively, would indicate that they were isomeric and not identical; this view, moreover, is borne out by an examination of other sulpho-products of the benzol series obtained by the use of these two reagents. This, the author thinks, might have been theoretically predicted if the conditions are considered under which the various substituted phenols are formed; the "reactive energy" of sulphuric acid being feeble compared with that of chlorine, for by its action on phenol it produces *meta*- and *para*-sulphonic acids, whilst chlorine in the cold gives rise to two chlorophenols; but by far the larger proportion of the mixture consists of *ortho*-chlorophenol. The "reactive energy" of the chlorhydric sulphate is far greater than that of sulphuric acid, being comparable in its action to chlorine rather than to sulphuric acid, and should, therefore, give rise to derivatives belonging to a different series. In all probability, however, there is a direct relation between the amount of heat evolved during the formation of a substitution derivative and the place it occupies in the isomeric series. The consideration, therefore, of the heat evolved in the formation of isomeric bodies would doubtless throw great light on the subject.

Dinitrochlorophenol melting at 130°.—This body, which was obtained by Stenhouse, by the action of chloride of iodine on picric acid, in the author's opinion is not identical with that prepared by Griess by nitrating crude chlorophenol, the latter being the β dinitrochlorophenol melting at 110° to 111°, especially as the amido-derivatives obtained from the two compounds differ considerably in appearance and properties. This discrepancy appears to have arisen from Griess's compound being contaminated with traces of the isomeride, melting at 80.5°. The author has also obtained trichlorophenol-sulphonic acid by acting on trichlorophenol with chlorhydric sulphate.

Professor WILLIAMSON remarked that these compounds were very interesting, particularly to those who had made the subject their especial study, and he should be very glad if Dr. Armstrong would give the members his opinion as to the difference between the action of hydric sulphate and chlorhydric sulphate, as he understood him to say that they only differed in degree.

Dr. ARMSTRONG replied that the question was one of so complex a character that he could not at present venture to give any opinion on the subject, but he believed that there was a direct relation between the amount of heat evolved during the reaction and the position which the resulting compound occupied in the series; he had undertaken some experiments in this direction, and hoped that the results would throw some light on this matter.

Dr. MULLER, in connection with the difference observed in the action of sulphuric and chlorhydric sulphate, called attention to the action of chlorine on toluol under varying conditions, producing chlorotoluol in the cold or in the presence of iodine, even when the latter is in comparatively small quantity, whilst at boiling heat it yields the isomeric benzylic chloride.

Dr. ARMSTRONG said that in the case of chlorhydric sulphate the action was not at all the same as that of sulphuric acid, being far more energetic and in that respect comparable to chlorine rather than to sulphuric acid. Again, iodine alone did not produce a substitution compound with benzol, but it did so when iodic acid was present; the action of the latter had been supposed to be due to its removing the hydriodic acid as soon as formed, but this would seem to be doubtful, as iodine in the presence of mercuric oxide produced iodine substitution compounds with benzol, and Lippmann had observed that amylene under similar circumstances gave compounds containing oxygen.

The meeting was then adjourned until Thursday, January 18, 1872.

GLASGOW PHILOSOPHICAL SOCIETY.

(CHEMICAL SECTION).

Ordinary Meeting, December 18th, 1871.

JOHN JEX LONG, Esq., Vice-President, in the Chair.

A PAPER was read by Mr. JOHN FERGUSON, M.A., Assistant Professor of Chemistry in the University of Glasgow, on "*Historical Notes on the Discoveries of Dr. Joseph Black.*" After briefly tracing the early life of Black, the author proceeded to notice his career as a student, first at the University of Glasgow and afterwards at the University of Edinburgh. In the former, Black was brought into intimate contact and personal friendship with Dr. Cullen, who was then the Professor of Chemistry in Glasgow, and it was under the tuition of that eminent philosopher that Black laid the foundation of his own future eminence as a chemist. Black afterwards went to Edinburgh, where he re-commenced and completed his medical studies, and while residing in that city his attention was specially taken up with the explanation of the facts connected with the difference of properties manifested by the caustic and so-called mild alkalies. It was this subject and his discovery of fixed air that he chose for his inaugural dissertation when he proceeded to take his medical degree. The author dwelt at considerable length on this dissertation, and treated it with marked critical ability. He showed how, step by step, Black arrived experimentally at the grand general conclusions which have now been universally accepted by the scientific world; and he gave him all due praise for the simplicity, perspicuity, and precision of his reasonings, while he at the same time regretted that Black, with such great abilities, had contributed so little to the sum total of the science of chemistry. Mr. Ferguson also referred to Black's discovery of the principle of latent heat, and to his career as a Professor in Glasgow and afterwards in Edinburgh, and in both cases in succession to his former master and friend, Dr. Cullen. A few remarks were also made in reference to the relationship in which Black and Lavoisier stood to each other as men of science.

A brief discussion followed, in the course of which Mr. SUTHERLAND took exception to the unfavourable estimate formed of Lavoisier by Mr. Ferguson, to which that gentleman replied that if it were thought that he had done Lavoisier any injustice, he would willingly go over the whole subject of his life again, and give the results of his inquiries to the section. He also stated, in reply to a question, that he was not sure that Priestley's discovery of oxygen was published in this country before the fact was communicated to Lavoisier.

A most cordial vote of thanks was awarded to Mr. Ferguson for his exceedingly interesting paper.

NOTICES OF BOOKS.

A Systematic Handbook of Volumetric Analysis; or the Quantitative Estimation of Chemical Substances by Measure, Applied to Liquids, Solids, and Gases. By FRANCIS SUTTON, F.C.S., Norwich. Second Edition. London: Churchill. 1871.

THE second edition of Mr. Sutton's well-known work on Volumetric Analysis, fully realises any expectations that may have been formed by chemists using the former edition of this handbook. Many changes have occurred in the theoretical chemistry since the issue of the first edition seven years ago, and general advance has been made in chemical analysis, but there is nothing remarkable in the

progress of volumetric analysis as a method, although its application has been greatly extended. The usefulness of the work has been much increased by the additions made by Dr. Frankland and Mr. W. Thorpe, F.C.S., to the subject of water analysis. The analysis of gases has been elaborated by Professor McLeod of the Indian Civil Engineering College, whose labours in relation to this subject are well known. The extensive illustration of this section of the work prevents the quotation, with fairness to Mr. Sutton, of any matter likely to interest our readers. The modern system of atomic weights has been adopted in this edition. There has been much done to render the work easily understood in the technical laboratory to which this method of analysis is peculiarly suited. It is too generally considered a standard work to require any further recommendation.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, December 4, 1871.

In addition to several important original papers and memoirs relating to astronomy, meteorology, geology, and natural history, this number contains the following original papers more particularly bearing upon chemistry:—

Separation of some Metals from each other, and Quantitative Estimation thereof by means of a Galvanic Current.—Dr. Lecoq de Boisbaudran.—After first referring to his former researches on this subject, the author states that it is by no means difficult to separate the more readily reducible metals when in acid solution from the less readily reducible metals present in the same solution, by the application of a moderately strong galvanic current; in this way the different metals may be classed in groups. As regards such metals as cobalt, nickel, and zinc, they are best precipitated from solutions containing excess of ammonia. Iron cannot be well estimated by this process because peroxide is formed.

Observation on Mr. Ritter's Paper on the Formation of Urea from Albuminoid Matter by the Action of Permanganate of Potassa.—A. Béchamp.—The contents of this paper simply bear upon the fact that the author, many years ago, discovered and published in various scientific periodicals some particulars which Ritter (see CHEMICAL NEWS, vol. xxiv., p. 288) states to be new.

New Method of Preparing the so-called Supersaturated Solutions.—L. C. de Coppet.—Anhydrous sulphate of soda, and likewise anhydrous carbonate of soda, and partly dehydrated sulphate of magnesia, are employed by the author to produce with cold water so concentrated solutions of the salts alluded to that, upon some small crystal of any of these salts being immersed into these solutions, they at once crystallise. It is, however, necessary for the success of the experiment that the salts be added to the water in small quantities at a time; by doing this carefully it is possible to dissolve in cold water five times as much anhydrous sulphate of soda, as water of the same temperature will keep in solution of the salt $\text{Na}_2\text{SO}_4, 10\text{H}_2\text{O}$.

Comparison between Two Kinds of Arable Soil, One of which was Formerly Woodland, the Other a Partly Broken-Up and Limed Soil.—Th. Schloßing.—The author records a series of experiments made with samples of surface soil and subsoil, taken from a locality in the Département de la Manche, chiefly with the view of ascertaining the effects, both physical and chemical, of the liming and non-liming of soils of a very poor nature. One of the effects of liming appears to be the conversion of chloride of sodium present in the soil into chloride of calcium, while nitrification also appears to be promoted by the lime. The greater part of the contents of this elaborate essay is of local interest only.

Testing and Quantitative Estimation of Arachis Oil in Olive Oil.—A. Renard.—The author bases this process upon the detection of arachidic acid. A quantity of 10 grms. of the oil to be tested is first saponified; the soap obtained having been decomposed by hydrochloric acid, the fatty acids set free are dissolved in 50 c.c. of alcohol at 95 per cent, the warm solution is precipitated by acetate of lead, and filtered after having become cold. The residue on the filter is treated with very strong and pure ether, which dissolves the oleate of lead, leaving margarate, palmitate, and arachidate of that metal. This compound

is heated, and then treated with warm dilute hydrochloric acid; the fatty acids are separated by decantation from the solution of chloride of lead. When the fatty acids are cooled, and thereby solidified, the cake thus obtained is dissolved in 50 c.c. of alcohol at 95 per cent by the aid of heat; a single drop of hydrochloric acid may have to be added to this solution in order to render it free from a slight cloudiness. If the olive oil operated upon happens to contain arachis oil, there will separate from the alcoholic solution, on cooling, crystals of arachidic acid. In order to estimate the quantity thereof, the crystalline mass is collected on a filter, first washed with a quantity of from 10 to 20 c.c. of the strong alcohol just alluded to, and next with ordinary alcohol, wherein this acid is insoluble. The substance upon the filter is next treated with boiling hot absolute alcohol, wherein the acid is dissolved, the filtrate collected in a previously weighed capsule, and the residue, left after a carefully conducted evaporation, weighed. The fusion-point of arachidic acid, obtained in this manner, is about 71°; of the pure substance, 73°. The author enters further into lengthy details as to the method of estimating the minute quantity of the arachidic acid dissolved (and therefore not collected along with the great bulk) in the strong alcohol used in these operations; the process is such that it may with due care yield very accurate results. Arachis oil is better known as ground-nut oil.

Composition of Lignites, and the Heat they Yield by Combustion.—Drs. Scheurer-Kestner and C. Meunier.—The authors communicate in this lengthy essay another portion of their very valuable and excellent researches on fossil fuel; this paper records the analysis of six different samples of lignite, three from Bohemia, obtained from different localities in France, and three from Met with: The analyses give—(1) The composition of the mineral as met with; (2) of the same, deducting ash and hygroscopic water; (3) the composition of the volatile portion of the mineral, less the water; next, the heat evolved by combustion as found by experiments is quoted; further, the calculated caloric; and, lastly, the sum of the caloric due to the combustion of the elements of which the lignites are composed. Lignite, the authors found, is distinguished from coal also in this particular—that the latter emits a far greater quantity of heat than that due to the combustion of its elements (carbon and hydrogen). Attention is again called to the fact that it is impossible to judge of the value of a fuel according to its elementary composition; all calculations based upon such data are quite fallacious, and the authors prove this conclusively by referring especially to one of the samples of lignite they investigated.

Analysis of Cows' Milk Taken from the Animals while Attacked by Typhus.—Dr. Hussou.—The milk of twenty-two cows, belonging to the same proprietor (of which number four were so badly attacked by contagious typhus as to necessitate the immediate killing of the same, while another batch of four were apparently quite well, and fourteen in a doubtful condition), has been investigated by the author. It appears that, as compared with the composition of normal milk, the milk of all these animals became more or less altered as regards the quantity of normal constituents, and may be termed very poor; yet, with the exception of the milk taken from the four cows which were very ill, there was nothing disagreeable about these samples of milk, and of the milk, which had got a bad taste and colour, a cat drank some 50 grms. without experiencing any bad effects. The author draws this conclusion, among others, from his researches—that neither the milk nor meat from cows so diseased can give the disease to men or other animals not belonging to the *Ruminantia*; yet, very properly, the author urges that severe measures should be taken to prohibit the use of milk as well as meat of cattle even suspected to be attacked by contagious typhus to be used as food; in fact, the milk, even at the first beginning of the disease, is entirely altered chemically as well as in its histological characters, as revealed by the microscope. Samples of milk:—A. From the apparently healthy cows. B. From the least ill. C. From the worst ill. The Sample A appeared to be milk in its normal condition; the two other samples exhibited a yellowish rose-red hue, and the taste of Sample C was very disagreeable. In 1000 grms. the samples contained:—

	A.	B.	C.	Average Composition of Milk in its normal state.
Butter	10'96	14'93	12'60	30
Milk sugar ..	33'90	31'40	16'45	50
Caseln	"	50'25	"	34
Albumen	"	20'60	"	6
Salts	"	18'50	"	7

New Researches on the so-called Widmannstittien Figures.—Dr. S. Meunier.—The author states that when a piece of meteoric iron is fixed to the positive pole of a Bunsen battery, the other pole being a piece of silver, and the electrodes are placed in an aqueous solution of bisulphate of potassa, and contact made, there will appear on the iron an iridescent colouration akin to the colouration brought about by heating the polished iron; if no contact takes place, there is produced upon the iron a figure similar to that which acids produce, but by this method it is more readily and more neatly brought out.

Progress Made in the Chemical Works Situated in the Valley of the Sambre (Belgium) in the Condensation of Noxious Vapours.—Dr. J. T. P. Chandelon.—This exhaustive and very important essay is the published reproduction of a report made by the author to the Belgian Minister of Home Affairs, and may be considered akin to the reports annually made by the Inspector under the Alkali Act, and published in this country; but, in this instance, the sulphuric acid manufactories are included, and the arrangement of the memoir is retrospective—that is to say, the present condition of all the chemical works alluded to is compared with the condition prevailing a few years ago. It appears that a very general improvement has taken place in every respect, and notably, also, in the quantity of sulphuric acid obtained from a given quantity of sulphur burnt in the shape of pyrites. The condensation of hydrochloric acid resulting from the decomposition of common salt in the alkali-works is also very complete.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
November 30, 1871.

Preparation of Pyrophosphate of Lime for Agricultural Purposes.—E. Deligny.—The coprolites, or other native tribasic phosphate, or bone-ash, is first treated with hydrochloric acid, and the mixture thus obtained dried in reverberatory furnace, leaving a pyrophosphate of lime, which, according to the author, contains 55 per cent of phosphoric acid, while the hydrochloric acid used is—at least in a great measure—recovered. The reaction is based upon the fact observed by the author, that from a mixture of acid phosphate of lime and chloride of calcium, when heated to 100°, the hydrochloric acid is driven off by the acid phosphate, leaving a dibasic phosphate, which is very readily assimilated by plants.

Use of Manure for Beet-roots.—M. Pagnoul.—It appears, from the contents of this paper, that soluble alkaline chlorides are not only not required for the healthy development of beet-roots, but that, these salts cause the roots to become less filled with saccharine juice. The quantity of alkaline carbonates left, after the incineration of the organic substance of the roots, as ash, and derived from organic salts present in the root, appears to decrease with an increase of the sugar; yet the author states that, whereas alkaline chlorides are not necessary to the life and development of beet-roots, alkaline carbonates ought, in small quantity, to be present, either in the soil wherein the roots grow or in the manure supplied to them, otherwise a healthy growth is not possible.

Continuation and End of the Lengthy Essay on the Chemical Dissociation of Bodies.—C. Mène.

Apparatus for the Combustion of Petroleum Oils to be used as Fuel.—H. Sainte Claire Deville and M. Wiesnegg.—This paper is illustrated by a woodcut. The furnace and accessory contrivances appear to be well suited for laboratory use when made on the small scale, and for manufacturing purposes when constructed in large size; the heat developed is very great, and there is no inconvenience of ash or smoke.

December 7, 1871.

On Fermentation in General.—C. Mène.—This paper is an excellent and very clearly written account of fermentation as understood by the ancients, the alchemists, the iatro-chemists. The microscopic researches made on ferment in 1680 by Antony van Leeuwenhoek are also briefly stated.

Process of Purification of the Crude Suet of Commerce.—J. Costhelys.—The author describes at length a process of purifying such fat-tallow as has been rendered, as it is termed, by the aid of sulphuric acid. The new process here described aims at the refining of the tallow, so that it may be used as dripping. From what is stated it appears that the result is, as was practically tested in Paris during the late siege, highly satisfactory.

New Rheometric Regulator for Gas-Burners.—M. Girond.—The contents of this valuable paper, illustrated by woodcuts, make us acquainted with a very ingeniously contrived regulator for gas-burners, whereby the consumers of gas who apply it to their burners have a perfect control over the quantity of gas consumed by each burner in a given time. As regards the further details on this subject, it would require the reproduction of the woodcuts. We hope the author will introduce this useful instrument in this country.

New Use for Silicate of Soda.—C. Mène.—The substance alluded to, in rather concentrated state, is first mixed with zinc-white (oxide of zinc of commerce), and may then be, as is actually the case in France, used as an excellent and resisting paint for out-door work on wood, metal, stone, paper, roofing felt, &c. Combustible substances coated with this material are, moreover, rendered unflammable.

L'es Mondes, December 14, 1871.

Extraordinary Cold Weather.—Rev. F. Moigno.—On Saturday, December 9th, the reading of the thermometer at the National Observatory at Paris was, in the morning (8 o'clock), -21.92° = about -7° F. Never since January 23rd, 1788, has the temperature been so low in Paris; at the Montsouris Observatory, situated beyond Paris proper, in the suburbs, the reading on the same day and hour was -23.7° . The late Arago states, in his work on Astronomy, that the lowest temperature observed in Paris since 1665 was -23.5° , on January 25th, 1795.

Revue Universelle des Mines, de la Metallurgie, des Travaux Publics des Sciences et des Arts Appliqués à l'Industrie, July and August, 1871.

In addition to important original papers on mining and on safety-valves of steam-boilers, this number contains the following original memoir relating to chemistry:—

Newly-invented Apparatus for Evaporating Liquids.—A. Wérotte.—An ingenious contrivance, illustrated by a woodcut. The apparatus is designed for evaporation on the large scale.

Although not exactly belonging to the subjects usually treated in our columns, we quote the title of the following work, which is highly spoken of in the above-named periodical:—"Dictionnaire Général des Forêts, Législation et Administration, recueil complet comprenant le résumé et l'analyse des lois, règlements, ordonnances, arrêts, décisions, &c., concernant les forêts depuis 1672 jusqu'au 1 Janvier, 1871," par A. Rosset, Sous-Inspecteur des Forêts. 2 vols., avec planches et modèles publié chez l'auteur à Nice, rue Cassini, 15. 1871.

December 21, 1871.

Observatory on the Puy de Dôme.—Rev. F. Moigno.—The locality alluded to is a rather elevated mountain situated in the Département of the same name, and not very far distant from the city of Clermont-Ferrand. It appears that, just previous to the breaking out of the late war Dr. Alluard, Professor of Natural Philosophy at the city above named, had proposed to the French Government to establish an observatory on the top of the mountain just named; to establish in the city laboratory, to which a special room for meteorological observations should be attached; and to construct a line of telegraph wires, to communicate, on the one hand with the two establishments, and on the other, by a separate wire, with the Observatory at Paris. The present French Government and the local departmental and municipal governments, having had this plan surveyed, have agreed to execute the necessary works at once.

Some Observations and Objections on the Supersaturation of Liquids by their own Vapour.—Rev. Father Sanna Solaro, S.J.—This very lengthy essay bears upon a portion of Mr. Tomlinson's paper which was reproduced in the above-named periodical. We reserve this paper for full translation.

Preservation and Improvement of Beet-Root Leaves to be Used as Fodder for Cattle.—Dr. Méhay.—The process here described essentially consists in steeping for a few minutes the leaves and heads of the beet-roots in weak hydrochloric acid (4° Baumé = 1.027 sp. gr.), leaving the vegetable matter to drain for a moment, after which it is placed in heaps into a kind of tank-like hole dug into the soil, care being taken to line its bottom and sides with straw. When filled the heap is first lightly covered with straw and then with earth—in fact, arranged in the manner used for preserving potatoes, carrots, &c. From the testimony of competent agriculturists and veterinary surgeons, the process here alluded to is indeed to be recommended for its good effect upon the cattle fed by vegetable matter thus preserved.

La Revue des Scientifique de la France et de l'Etranger,
December 16, 1871.

This number does not contain any original papers relating to chemistry.

Journal für Praktische Chemie, No. 18, 1871.

This number contains the following original memoirs and papers:—

On the Compounds of Tin and Titanium Crystallising from Glassy Fluxes, namely, Fused Beads obtained by the Blowpipe Flame.—G. Wunter.—The contents of this paper record a series of chemico-crystallographical experiments made by the author with a view to ascertain whether it is possible to obtain definite crystalline compounds and titanate acid by fusing together oxide of tin with borax and phosphor salt; the method of analysing these substances is also fully described. Among the tin compounds we quote the formulæ of the following:—

Rhombohedral.

Tetragonal pyramids.

$\text{SnNa}_2(\text{PO}_3)_4$ pyramids in 200 parts:— SnO_2 , 42.37; P_2O_5 , 40.11; Na_2O , 17.51. Rhombohedra, $\text{Sn}_2\text{Na}(\text{PO}_3)_4$, in 100 parts:— SnO_2 , 54.82; P_2O_5 , 39.44; Na_2O , 5.74. Titanium compound, $\text{TiO}_2\text{Na}(\text{PO}_3)_4$:— TiO_2 , 40.80; P_2O_5 , 52.20; Na_2O , 7.60.

Relation Existing between the Specific Gravity of, and the Quantity of Pigment contained in, Indigo.—G. Leuchs.—The author relates a series of experiments quoted in tabulated form, exhibiting the sp. gr. of various samples of indigo and the quantity of indigotine therein contained, the latter particular being estimated by a process described in one of the earlier published volumes of this periodical; it appears that in forty-nine different samples of dye-stuff alluded to, the best contained 60.5 per cent of indigotine and the worst 24 per cent, the sp. gr. of the former being low and the latter high.

Mineralogical Miscellany.—A. Frenzel.—This paper contains the following sections:—Lithiophorite; hypochlorite; pucherite.

Preparation of Carboxycyanide.—Dr. W. F. Gintl.—At present this paper contains only an incomplete account of the author's researches on this subject now made public in consequence of an account of similar researches having been lately published by other German savants. A complete account of this investigation will be given.

On Hygienico-Chemical Methods of Investigation.—Dr. H. Fleck.—First instalment. Detection and estimation of organic matter in water. Reserved for full translation; an observation also applicable to the following paper:—

Determination of Ammonia in River and Well Waters by Means of Nessler's Test.—E. Schürmann.

Electrolysis of Itaconic Acid.—G. Aarland and E. Carstensen.—After first referring to Kekulé's, Kolbe's, and Liebermann's experiments on the electrolysis of some organic acids, the authors describe the method of experimenting with itaconic acid, which is decomposed by the electric current, yielding carbonic acid and allylen, C_3H_4 .

Monochloracetate and Amidonacetate of Phenol.—E. W. Prevost.—Monochloracetate of phenol smells like phenol, exhibits an acid reaction, is insoluble in water, readily soluble in alcohol and ether, fuses at 40°; formula, $\text{C}_6\text{H}_5\text{O}(\text{C}_2\text{H}_4\text{ClO})$; when this compound is heated up to 140° along with ammoniacal alcohol in a sealed tube, there is formed amido-acetate of phenol, $\text{C}_6\text{H}_5\text{O}(\text{C}_2\text{H}_4\text{H}_2\text{N}_2\text{O})$, a crystalline white-coloured body, acid reaction, soluble in water, almost insoluble in alcohol and ether; may be heated to 133° without undergoing any other change than becoming soft; at a higher temperature it is decomposed.

Probable Existence of Two Oxysulphides of Carbon.—Dr. H. Kolbe.—The contents of this paper are devoted to a theoretical discussion of what may be, though not yet experimentally proved to be, the result of the decomposition of sulphocyanide of potassium and isosulphohydrocyanic acid under the influence of sulphuric acid. The author illustrates this subject by a series of formulæ, and intimates that one of his assistants has commenced experimental researches on this subject.

NOTES AND QUERIES.

Residue from Olive Oil Presses.—Can your readers inform me if it is possible, and where, and how, I can obtain some of the residue from olive oil presses; I mean the fruit which remains after the oil is pressed out.—OLEUM.

Dehydrating Oxalic Acid.—(Reply to "Q. R.")—Crystallised oxalic acid = $\text{HO}_2\text{C}_2\text{O}_4 \cdot 2\text{aq}$. The dehydrated $\text{HO}_2\text{C}_2\text{O}_4$ can be obtained by drying the crystallised acid at 100°, or at almost 120°. Oxalic ether cannot be made in the way proposed by you, but is made by distilling a mixture of an oxalate along with strong alcohol and strong sulphuric acid. Dr. Miller's excellent work on Chemistry will give you full particulars.

Adulterations in Food and Drink.—(Reply to "An Amateur Chemist.")—You will find the work published under the following title a valuable and reliable aid:—"Die wichtigsten Lebensbedürfnisse, ihre Aechtheit und Güte, ihre Zufälligen Verunreinigungen und ihre Absichtlichen Verfälschungen mit gleichzeitiger Berücksichtigung der in Haushaltung, den Künsten und Gewerben Benutzten Chemische Gifte (Polizeilich-Gerichtliche Chemie)," von Dr. Adolf Duflos (Breslau; F. Hirt).

NOTICE TO AMERICAN SUBSCRIBERS.

In answer to numerous inquiries, the Publisher begs to state that Subscribers in the United States can be supplied with the CHEMICAL NEWS from this Office, post free, for the sum of £1 2s. 4d. per annum payable in advance.

THE QUARTERLY JOURNAL OF SCIENCE, AND

ANNALS OF MINING, METALLURGY, ENGINEERING, INDUSTRIAL ARTS
MANUFACTURES, AND TECHNOLOGY.

Edited by WILLIAM CROOKES, F.R.S., &c.

This day, No. XXXIII., January, 1872, price 5s., Illustrated.

CONTENTS.

- I. The Dolmen-Mounds and Amorpholitic Monuments of Brittany. By S. P. OLIVER, Capt. Royal Artillery, F.R.G.S.
- II. The Illumination of Beacons and Buoys.
- III. Natural and Artificial Flight. With Seven Woodcuts.
- IV. The Coal Commissioners' Report.
- V. The Spectroscope: its Imperfections and their Remedy.
- VI. Modern Cannon Powder. With Three Page Plates.

Notices of Books. Progress of the Various Sciences. Recent Scientific Literature, &c., &c.

London: Offices of the Quarterly Journal of Science, 3, Horse-Shop Court, Ludgate Hill, E.C.

TEXT-BOOKS OF SCIENCE.

Now ready, in small 8vo., price 3s. 6d.,

The Theory of Heat. By J. Clerk Maxwell, M.A., F.R.S.S. L. & E., Professor of Experimental Physics in the University of Cambridge.

Being the Sixth of the New Series of Elementary Works on Mechanical and Physical Science in course of publication, edited by Professor T. M. Goodave, M.A.

Text-Books previously published, price 3s. 6d. each:—

1. GOODEVE'S MECHANISM.
2. BLOXAM'S METALS.
3. MILLER'S INORGANIC CHEMISTRY.
4. GRIFFIN'S ALGEBRA AND TRIGONOMETRY.
5. WATSON'S PLANE AND SOLID GEOMETRY.

London: Longmans, Green, and Co., Paternoster Row.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of **PRACTICAL CHEMISTRY**, particularly in its application to **MEDICINE, AGRICULTURE, and COMMERCE.**

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake **ANALYSES** of every description.

For Particulars and Prospectuses, apply to **Mr. Henry Matthews**, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE OF CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor **E. V. GARDNER, F.R.S., &c.**: of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open daily. Especial facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For particulars, &c., apply to Prof. **E. V. G.**, 44, Berners-street, W.

ANALYTICAL LABORATORY and SCHOOL OF TECHNICAL CHEMISTRY.

7 and 9, HACKIN'S HEY, LIVERPOOL.

Conducted by **A. NORMAN TATE**, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied and the erection of Plant and Buildings is superintended when required.

AMSTERDAM EXHIBITION, 1869.

The **GRAND DIPLOMA of HONOUR**, being the First Prize, and **SUPERIOR to the Gold Medal.**

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by **BARON LIEBIG**, the Inventor. "A succuss and a boon"—Medical Press and Circular. One pint of delicious beef-tee for 2½d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require **BARON LIEBIG's** signature upon every jar Sold by all Italian Warehousemen, Grocers, Chemists, and Ships. Store Dealers; all Wholesale Houses; and of **LIEBIG'S EXTRACT of MEAT COMPANY (LIMITED)**, 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tee made from Liebig Company's Extract with *boiling-hot water* will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British French, Prussian, Russian and other Governments.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By **THOMAS RICHARDSON and HENRY WATTS.** Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE and Co., 20, King William Street, Strand.

New Laboratory Apparatus:—

CENTRE BLAST BUNSEN, combining a Bunsen, and a very powerful Herapath, 10s. 6d.

HOT-BLAST BLOWPIPE, giving the temperature exceeding the fusing-point of platinum, 9s. 6d.

TABLE FURNACE, without blast, for operations below a white heat, 30s.

The above were awarded the first medal of the Royal Cornwall Polytechnic Society, 1871. Drawings, &c., one stamp.

T. FLETCHER, 15, BOLO ST., WARRINGTON.

Methylated Spirits.—**David Smith Kidd**, Licensed Maker, Commercial Street, Shoreditch, N.E. Also **FINISH, FUSEL OIL, and RECT. NAPHTHA.**

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at **ROBERT RUMNEY'S**, Ardwick Chemical Works, Manchester.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by **W. GOSSAGE and Sons**, Widnes Soapery, Warrington.

London Agents, **CLARKE and COSTE**, 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

ESTABLISHED 1798.

ROBERT DAGLISH & CO.,
BOILER MAKERS, ENGINEERS, AND
MILL-WRIGHTS,
BRASS AND IRONFOUNDERS,
ST. HELEN'S FOUNDRY, LANCASHIRE.

Makers of every description of Chemical, Colliery, Copper Ore Mining, and Glass Machinery, including Crown, German Sheet, and Plate Glass Plant, as supplied to some of the largest Firms in England, Ireland, Scotland, and Wales.

Makers of the latest Improved Revolving Black Ash Furnace, with Siemens's Patent Gas Arrangement, and as used in the Manufacture of Soda.

Improved Vertical Blowing Engines (which have given a much higher Blast than any others have yet obtained), and as supplied to the entire satisfaction of most of the largest Bleaching Powder Manufacturers who have adopted "Weldon's Patent Process."

Authorised by Patentee to supply the Ironwork and Plant required in the Manufacture of Bleaching Powder by "Deacon's Patent."

Plans and Estimates of the Plant required for working these Patents in accordance with the Patentee's instructions.

Photographs, Prices, and other information, supplied on receipt of Order.

FLUOR SPAR.
LEVIGATED SULPHATE OF BARYTES.
CHLORIDE OF BARIUM.

Mr. Matthew Greene, 14, Pinner's Hall, London, E.C., is in a position to supply the above articles on the best terms. Samples and prices on application.
